In addition to these intracellular inhibitors, a number of secreted extracellular inhibitory proteins can also neutralize signaling mediated by TGF- β family members. They directly bind to the signal molecules and prevent them from activating their receptors on target cells. *Noggin* and *chordin*, for example, inhibit BMPs, and *folistatin* inhibits activins. Noggin and chordin help to induce the development of the vertebrate nervous system by preventing BMPs from inhibiting this development (discussed in [Chapter 21](#)). The TGF- β family members, as well as some of their inhibitors, are usually secreted as inactive precursors that are subsequently activated by proteolytic cleavage.

We turn now to enzyme-linked receptors that are neither kinases nor associated with kinases. We saw earlier that nitric oxide is widely used as a signaling molecule, diffusing through the plasma membrane of a target cell and stimulating a cytoplasmic guanylyl cyclase to produce the intracellular mediator cyclic GMP. The receptors we now consider are transmembrane proteins with guanylyl cyclase activity. [↑ TOP](#)

Receptor Guanylyl Cyclases Generate Cyclic GMP Directly

Receptor guanylyl cyclases are single-pass transmembrane proteins with an extracellular binding site for a signal molecule and an intracellular guanylyl cyclase catalytic domain. The binding of the signal molecule activates the cyclase domain to produce cyclic GMP, which in turn binds to and activates a

cyclic GMP-dependent protein kinase (PKG), which phosphorylates specific proteins on serine or threonine. Thus, receptor guanylyl cyclases use cyclic GMP as an intracellular mediator in the same way that some G-protein-linked receptors use cyclic AMP, except that the linkage between ligand binding and cyclase activity is a direct one.

Among the signal molecules that use receptor guanylyl cyclase receptors are the *natriuretic peptides (NPs)*, a family of structurally related secreted signal peptides that regulate salt and water balance and dilate blood vessels. There are several types of NPs, including *atrial natriuretic peptide (ANP)* and *brain natriuretic peptide (BNP)*. Muscle cells in the atrium of the heart secrete ANP when blood pressure rises. The ANP stimulates the kidneys to secrete Na^+ and water and induces the smooth muscle cells in blood vessels walls to relax. Both of these effects tend to lower the blood pressure. When gene targeting is used to inactivate the ANP receptor guanylyl cyclase in mice, the mice have chronically elevated blood pressure, resulting in progressive heart enlargement.

An increasing number of receptor guanylyl cyclases are being discovered, but in most cases they are orphan receptors, where the ligand that normally activates them is unknown. The genome of the nematode *C. elegans*, for example, encodes 26 of these receptors. Most of those that have been studied are expressed in specific subsets of sensory neurons, suggesting that they may be involved in detecting particular molecules in the worm's environment. Some of the orphan receptors in mammals are found in sensory neurons in the part of the nose involved in detecting pheromones.

All the signaling pathways activated by G-protein-linked and enzyme-linked receptors we have discussed so far depend on serine/threonine-specific protein kinases, tyrosine-specific protein kinases, or both. These kinases are all structurally related, as reviewed in [Figure 15-66](#). Some enzyme-linked receptors, however, depend on an entirely unrelated type of protein kinase, as we now discuss.  [TOP](#)

Bacterial Chemotaxis Depends on a Two-Component Signaling Pathway Activated by Histidine-Kinase-associated Receptors

As pointed out earlier, many of the mechanisms involved in chemical signaling between cells in multicellular animals are thought to have evolved from mechanisms used by unicellular organisms to respond to chemical changes in their environment. In fact, some of the same intracellular mediators, such as cyclic nucleotides and Ca^{2+} , are used by both types of organisms. Among the best-studied reactions of unicellular organisms to extracellular signals are their chemotactic responses, in which cell movement is oriented toward or away from a source of some chemical in the environment. We conclude this section on enzyme-linked receptors with a brief account of bacterial chemotaxis, which depends on a **two-component signaling pathway**, involving histidine-

kinase-associated receptors. The same type of signaling pathway is used by yeasts and plants, although apparently not by animals.

Motile bacteria will swim toward higher concentrations of nutrients (*attractants*), such as sugars, amino acids, and small peptides, and away from higher concentrations of various noxious chemicals (*repellents*). They swim by means of flagella, each of which is attached by a short, flexible hook at its base to a small protein disc embedded in the bacterial membrane. This disc is part of a tiny motor that uses the energy stored in the transmembrane H^+ gradient to rotate rapidly and turn the helical flagellum (Figure 15-67). Because the flagella on the bacterial surface have an intrinsic "handedness," different directions of rotation have different effects on movement. Counterclockwise rotation allows all the flagella to draw together into a coherent bundle, so that the bacterium swims uniformly in one direction. Clockwise rotation causes them to fly apart, so that the bacterium tumbles chaotically without moving forward (Figure 15-68). In the absence of any environmental stimulus, the direction of rotation of the disc reverses every few seconds, producing a characteristic pattern of movement in which smooth swimming in a straight line is interrupted by abrupt, random changes in direction caused by tumbling.

The normal swimming behavior of bacteria is modified by chemotactic attractants or repellents, which bind to specific receptor proteins and affect the frequency of tumbling by increasing or decreasing the time that elapses between successive changes in direction of flagellar rotation. When bacteria are swimming in a favorable direction (toward a higher concentration of an attractant or away from a higher concentration of a repellent), they tumble less frequently than when they are swimming in an unfavorable direction (or when no gradient is present). Since the periods of smooth swimming are longer when a bacterium is traveling in a favorable direction, it will gradually progress in that direction—toward an attractant or away from a repellent.

These responses are mediated by histidine-kinase-associated **chemotaxis receptors**, which typically are dimeric transmembrane proteins that bind specific attractants and repellents on the outside of the plasma membrane. The cytoplasmic tails of the receptors are stably associated with an adaptor protein *CheW* and a histidine kinase *CheA*, which help to couple the receptors to the flagellar motor. Repellent binding activates the receptors, whereas attractant binding inactivates them; a single receptor can bind either type of molecule, with opposite consequences. The binding of a repellent to the receptor activates *CheA*, which phosphorylates itself on a histidine and almost immediately transfers the phosphate to an aspartic acid on a messenger protein *CheY*. The phosphorylated *CheY* dissociates from the receptor, diffuses through the cytosol, binds to the flagellar motor, and causes the motor to rotate clockwise, so that the bacterium tumbles. *CheY* has intrinsic phosphatase activity and dephosphorylates itself in a process that is greatly accelerated by the *CheZ* protein (Figure 15-69).

The response to an increase in the concentration of an attractant or repellent is only transient, even if the higher level of ligand is maintained, as the bacteria *desensitize*, or *adapt*, to the increased stimulus. Whereas the initial effect on tumbling occurs in less than a second, adaptation takes minutes. The adaptation is a crucial part of the response, as it enables the bacteria to respond to *changes* in concentration of ligand rather than to steady-state levels. It is mediated by the covalent methylation (catalyzed by a methyl transferase) and demethylation (catalyzed by a methylase) of the chemotaxis receptors, which change their responsiveness to ligand binding when methylated.

All of the genes and proteins involved in this highly adaptive behavior have now been identified. It therefore seems likely that bacterial chemotaxis will be the first signaling system to be completely understood in molecular terms. Even in this relatively simple signaling network, computer-based simulations are required to comprehend how the system works as an integrated network. Cell signaling pathways will provide an especially rich area of investigation for a new generation of computational biologists, as their network properties will not be understandable without powerful computational tools.

There are some cell-surface receptor proteins that do not fit into the three major classes we have discussed thus far—ion-channel-linked, G-protein-linked, and enzyme-linked. In the next section, we consider cell-surface receptors that activate signaling pathways that depend on proteolysis. These pathways have especially important roles in animal development. [↑ TOP](#)

Summary

There are five known classes of enzyme-linked receptors: (1) receptor tyrosine kinases, (2) tyrosine-kinase-associated receptors, (3) receptor serine/threonine kinases, (4) transmembrane guanylyl cyclases, and (5) histidine-kinase-associated receptors. In addition, some transmembrane tyrosine phosphatases, which remove phosphate from phosphotyrosine side chains of specific proteins, are thought to function as receptors, although for the most part their ligands are unknown. The first two classes of receptors are by far the most numerous.

Ligand binding to receptor tyrosine kinases induces the receptors to cross-phosphorylate their cytoplasmic domains on multiple tyrosines. The autophosphorylation activates the kinases, as well as producing a set of phosphotyrosines that then serve as docking sites for a set of intracellular signaling proteins, which bind via their SH2 (or PTB) domains. Some of the docked proteins serve as adaptors to couple the receptors to the small GTPase Ras, which, in turn, activates a cascade of serine/threonine phosphorylations that converge on a MAP-kinase, which relays the signal to the nucleus by phosphorylating gene regulatory proteins there. Ras can also activate another protein that docks on activated receptor tyrosine kinases—PI 3-kinase—which generates specific inositol phospholipids that serve as docking sites in the plasma membrane for signaling proteins with PH domains, including protein

kinase B (PKB).

Tyrosine-kinase-associated receptors depend on various cytoplasmic tyrosine kinases for their action. These kinases include members of the Src family, which associate with many kinds of receptors, and the focal adhesion kinase (FAK), which associates with integrins at focal adhesions. The cytoplasmic tyrosine kinases then phosphorylate a variety of signaling proteins to relay the signal onward. The largest family of receptors in this class is the cytokine receptors family. When stimulated by ligand binding, these receptors activate Jak cytoplasmic tyrosine kinases, which phosphorylate STATs. The STATs then dimerize, migrate to the nucleus, and activate the transcription of specific genes. Receptor serine/threonine kinases, which are activated by signaling proteins of the TGF- β superfamily, act similarly: they directly phosphorylate and activate Smads, which then oligomerize with another Smad, migrate to the nucleus, and activate gene transcription.

Bacterial chemotaxis is mediated by histidine-kinase-associated chemotaxis receptors. When activated by the binding of a repellent, the receptors stimulate their associated protein kinase to phosphorylate itself on histidine and then transfer that phosphate to a messenger protein, which relays the signal to the flagellar motor to alter the bacterium's swimming behavior. Attractants have the opposite effect on this kinase and therefore on swimming. [↑ TOP](#)

Figure 15-50. Three ways in which signaling proteins can cross-link receptor chains. When the receptor chains are cross-linked, the kinase domains of adjacent receptors cross-phosphorylate each other, stimulating the kinase activity of the receptor and creating docking sites for intracellular proteins. (A) Platelet-derived growth factor (PDGF) is a covalently linked dimer with two receptor-binding sites, so it can directly cross-link adjacent receptors to initiate the intracellular signaling process. The PDGF dimers are composed of A and B chains in different combinations, and they can activate different combinations of two types of PDGF receptor chains (α and β), which have somewhat different signaling properties. (B) Some monomeric ligands, such as fibroblast growth factors (FGFs), bind in clusters to proteoglycans, enabling the ligands to cross-link their receptors. The proteoglycans can be in the extracellular matrix or, as shown here, on the cell surface. There are more than 20 types of FGFs and more than 4 types of FGF receptors. (C) Membrane-bound signaling proteins, such as ephrins, can cross-link their

receptors even though they are monomeric, because they cluster in the plasma membrane of the signaling cell. Some ephrins (B-type) are transmembrane proteins (as shown), whereas others (A-type) are linked to the membrane by a glycosylphosphatidylinositol (GPI) anchor (see [Figure 12-56](#)). For the most part, A-type ephrins activate A-type Eph receptors, and B-type ephrins activate B-type Eph receptors.

Figure 15-51. Inhibition of signaling through normal receptor tyrosine kinases by an excess of mutant receptors. (A) In this example, the normal receptors dimerize in response to ligand binding. The two kinase domains cross-phosphorylate each other, increasing the activity of the kinase domains, which can now further activate the receptor dimer by phosphorylating other sites on the receptors. (B) The mutant receptor with an inactivated kinase domain can dimerize normally, but it cannot cross-phosphorylate a normal receptor in a dimer. For this reason, the mutant receptors, if present in excess, will block signaling by the normal receptors—a process called *dominant-negative inhibition*. Cell biologists frequently use this strategy to inhibit a specific type of receptor tyrosine kinase in a cell to determine its normal function.

Molecular Biology of the Cell → **IV. Internal Organization of the Cell** → **15. Cell Communication** → **Signaling through Enzyme-Linked Cell-Surface Receptors**

Figure 15-53. The binding of SH2-containing intracellular signaling proteins to an activated PDGF receptor. (A) This drawing of a PDGF receptor shows five of the tyrosine autophosphorylation sites, three in the kinase insert region and two on the C-terminal tail, to which the three signaling proteins shown bind as indicated. The numbers on the right indicate the positions of the tyrosines in the polypeptide chain. These binding sites have

been identified by using recombinant DNA technology to mutate specific tyrosines in the receptor. Mutation of tyrosines 1009 and 1021, for example, prevents the binding and activation of PLC- γ , so that receptor activation no longer stimulates the inositol phospholipid signaling pathway. The locations of the SH2 (*red*) and SH3 (*blue*) domains in the three signaling proteins are indicated. (Additional autophosphorylation sites on this receptor are not shown, including those that serve as binding sites for the cytoplasmic tyrosine kinase Src and the adaptor proteins Grb2 and Shc, discussed later.) (B) The three-dimensional structure of an SH2 domain, as determined by x-ray crystallography. The binding pocket for phosphotyrosine is shown in *yellow* on the right, and a pocket for binding a specific amino acid side chain (isoleucine, in this case) is shown in *yellow* on the left (see also [Figure 3-40](#)). (C) The SH2 domain is a compact, "plug-in" module, which can be inserted almost anywhere in a protein without disturbing the protein's folding or function (see [Figure 3-19](#)). Because each domain has distinct sites for recognizing phosphotyrosine and for recognizing a particular amino acid side chain, different SH2 domains recognize phosphotyrosine in the context of different flanking amino acid sequences. Figure 15-54. The regulation of Ras activity. GTPase-activating proteins (GAPs) inactivate Ras by stimulating it to hydrolyze its bound GTP; the inactivated Ras remains tightly bound to GDP. Guanine nucleotide exchange factors (GEFs) activate Ras by stimulating it to give up its GDP; the concentration of GTP in the cytosol is 10 times greater than the concentration of GDP, and Ras rapidly binds GTP once GDP has been ejected. Several Ras-regulating GAPs (Ras GAPs) have been characterized in mammalian cells, including $p120^{GAP}$ and *neurofibromin* (so named because it is encoded by the gene that is mutated in the common human genetic disease neurofibromatosis, which is associated with tumors of nerves). The Ras GAPs maintain most of the Ras protein (~95%) in unstimulated cells in an inactive GDP-bound state.

Figure 15-56. The MAP-kinase serine/threonine phosphorylation pathway activated by Ras. Multiple such pathways involving structurally and functionally related proteins operate in all eucaryotes, each coupling an extracellular stimulus to a variety of cell outputs. The pathway activated by Ras begins with a MAP-kinase-kinase-kinase called *Raf*, which activates the MAP-kinase-kinase *Mek*, which then activates the MAP-kinase called *Erk*. *Erk* in turn phosphorylates a variety of downstream proteins, including other kinases, as well as gene regulatory proteins in the nucleus. The resulting changes in gene expression and protein activity cause complex changes in cell behavior.

Molecular Biology of the Cell → **IV. Internal Organization of the Cell** → **15. Cell Communication** → **Signaling through Enzyme-Linked Cell-Surface Receptors**

Figure 15-57. The organization of MAP-kinase pathways by scaffold proteins in budding yeast. Budding yeast have at least six three-component MAP-kinase modules involved in a variety of biological processes, including the two responses illustrated here—a mating response and the response to high osmolarity. (A) The mating response is triggered when a mating factor secreted by a yeast of opposite mating type binds to a G-protein-linked receptor. This activates a G protein, and the $\beta\gamma$ complex of the G protein indirectly activates the MAP-kinase-kinase-kinase (kinase A), which then relays the response onward. Once activated, the MAP-kinase (kinase C) phosphorylates and thereby activates several proteins that mediate the mating response, in which the yeast cell stops dividing and prepares for fusion. The three kinases in this module are bound to scaffold protein 1. (B) In a second response, a yeast cell exposed to a high-osmolarity environment is induced to synthesize glycerol to increase its internal osmolarity. This response is mediated by a transmembrane, osmolarity-sensing, receptor protein and a different MAP-kinase module bound to a second scaffold protein. (Note that the kinase domain of scaffold 2 provides the MAP-kinase-kinase activity of this module.) Although both pathways use the same MAP-kinase-kinase-kinase (kinase A, green), there is no cross talk between them, because the kinases in each module are tightly bound to different scaffold proteins, and the osmosensor is bound to the same scaffold protein as the particular kinase it activates.

Molecular Biology of the Cell → IV. Internal Organization of the Cell → 15. Cell Communication → Signaling through Enzyme-Linked Cell-Surface Receptors

Figure 15-60. One way in which signaling through PI 3-kinase promotes cell survival. An extracellular survival signal activates a receptor tyrosine kinase, which recruits and activates PI 3-kinase. The PI 3-kinase produces PI(3,4,5)P₃ and PI(3,4)P₂ (not shown), both of which serve as docking sites for two serine/threonine kinases with PH domains—protein kinase B (PKB) and the phosphoinositide-dependent kinase PDK1. The binding of PKB to the inositol lipids alters its conformation so that the protein can be phosphorylated and activated by PDK1. The activated PKB now dissociates from the plasma membrane and phosphorylates the BAD protein, which, when unphosphorylated, holds one or more death-inhibitory proteins in an inactive state. Once phosphorylated, BAD releases the inhibitory proteins, which now can block programmed cell death (apoptosis) and thereby promote cell survival. As shown, once phosphorylated, BAD binds to a ubiquitous cytosolic protein called 14-3-3, which keeps BAD out of action. There are about 20 14-3-3 proteins in human cells, all of which bind to specific phosphoserine-containing motifs in proteins. The activation of other signaling pathways can also lead to BAD phosphorylation and the promotion of cell survival (not shown).

Figure 15-62. The three-dimensional structure of human growth hormone bound to its receptor. The hormone (*red*) has cross-linked two identical receptors (one shown in *green* and the other in *blue*). Hormone binding activates cytoplasmic tyrosine kinases that are tightly bound to the cytosolic tails of the receptors (not shown). The structures shown were determined by x-ray crystallographic studies of complexes formed between the hormone and extracellular receptor domains produced by recombinant DNA technology. It was entirely unexpected that a monomeric ligand such as growth hormone would cross-link its receptors, as it requires that the two identical receptors recognize different parts of the hormone. As mentioned earlier, EGF does the same thing. (From A.M. deVos, M. Ultsch, and A.A. Kossiakoff, *Science* 255:306–312, 1992. © AAAS.)

Figure 15-63. The Jak-STAT signaling pathway activated by α -interferon. The binding of interferon either causes two separate receptor polypeptide chains to dimerize (as shown) or reorients the receptor chains in a preformed dimer. In either case, the associated Jaks are brought together so that they can cross-phosphorylate each other on tyrosines, starting the signaling process. The two different receptor chains are associated with different Jaks (Tyk2 and Jak1), and they recruit different STATs (STAT1 and STAT2). The STATs dissociate from the receptors and form heterodimers when activated by phosphorylation, and they bind to specific DNA sequences in the cell nucleus, where, together with other gene regulatory proteins, they induce the transcription of adjacent genes.

Figure 15-65. A model for the Smad-dependent signaling pathway activated by TGF- β . Note that TGF- β is a dimer and that Smads open up to expose a dimerization surface when they are phosphorylated. Several features of the pathway have been omitted for simplicity, including the following: (1) The type-I and type-II receptor proteins are both thought to be dimers. (2) The type-I receptors are normally associated with an inhibitory protein, which dissociates when the type-I receptor is phosphorylated by a type-II receptor. (3) The individual Smads are thought to be trimers. (4) An anchoring protein (called SARA, for Smad anchor for receptor activation) helps to recruit Smad2 or Smad3 to the activated type I receptor by binding to the receptor, to the Smad, and to inositol phospholipid molecules in the plasma membrane. (5) The function of certain Smads is regulated by enzymes that enhance their ubiquitylation and thereby their degradation.

Figure 15-66. Some of the protein kinases discussed in this chapter. The size and location of their catalytic domains (*dark green*) are shown. In each case the catalytic domain is about 250 amino acids long. These domains are all similar in amino acid sequence, suggesting that they have all evolved from a common primordial kinase (see also [Figure 3-65](#)). Note that all of the tyrosine kinases shown are bound to the plasma membrane (Jaks are bound by their association with cytokine receptors), whereas most of the serine/threonine kinases are in the cytosol.

Figure 15-67. The bacterial flagellar motor. The flagellum is linked to a flexible hook. The hook is attached to a series of protein rings (shown in red), which are embedded in the outer and inner (plasma) membranes. The rings form a rotor, which rotates with the flagellum at more than 100 revolutions per second. The rotation is driven by a flow of protons through an outer ring of proteins (see Figure 14-17), the stator, which also contains the proteins responsible for switching the direction of rotation. Figure 15-69. The two-component signaling pathway that enables chemotaxis receptors to control the flagellar motor during bacterial chemotaxis. The histidine kinase CheA is stably bound to the receptor via the adaptor protein CheW. The binding of a repellent increases the activity of the receptor, which stimulates CheA to phosphorylate itself on histidine. CheA quickly transfers its covalently bound, high-energy phosphate directly to CheY to generate CheY-phosphate, which then diffuses away, binds to the flagellar motor, and causes the motor to rotate clockwise, which results in tumbling. The binding of an attractant has the opposite effect: it decreases the activity of the receptor and therefore decreases the phosphorylation of CheA and CheY, which results in counterclockwise flagellar rotation and smooth swimming. CheZ accelerates the autodephosphorylation of CheY-phosphate, thereby

inactivating it. Each of the phosphorylated intermediates decays in about 10 seconds, enabling the bacterium to respond very quickly to changes in its environment (see Figure 15-10).

Signaling Pathways That Depend on Regulated Proteolysis

The need for intercellular signaling is never greater than during animal development. Each cell in the embryo has to be guided along one developmental pathway or another according to its history, its position, and the character of its neighbors. At each step in the pathway, it must exchange signals with its neighbors to coordinate its behavior with theirs. Most of the signaling pathways already discussed are widely used for these purposes. But there are also others that relay signals in other ways from cell-surface receptors to the interior of the cell. These additional signaling pathways all depend, in part at least, on regulated proteolysis. Although most of them first came to light through genetic studies in *Drosophila*, they have been highly conserved in evolution and are used over and over again during animal development. As we discuss in [Chapter 22](#), they also have a crucial role in the many developmental processes that continue in adult tissues.

We discuss four of these signaling pathways in this section: the pathway mediated by the receptor protein *Notch*, the pathway activated by secreted *Wnt* proteins, the pathway activated by secreted *Hedgehog* proteins, and the pathway that depends on activation of the latent gene regulatory protein *NF-κB*. All of these pathways have crucial roles in animal development. If any one of them is inactivated in a mouse, for example, development is seriously disturbed, and the mouse dies as an embryo or at birth. (We discuss the roles of *Notch*, *Wnt*, and *Hedgehog* signaling in embryonic development in [Chapter 21](#).)

The Receptor Protein Notch Is Activated by Cleavage

Signaling through the *Notch* receptor protein may be the most widely used signaling pathway in animal development. As discussed in [Chapter 21](#), it has a general role in controlling cell fate choices during development, mainly by amplifying and consolidating molecular differences between adjacent cells. Although *Notch* signaling is involved in the development of most tissues, it is best known for its role in nerve cell production in *Drosophila*. The nerve cells

 Figure 15-74. The activation of NF- κ B by...

This book
books
PubMed

All

usually arise as isolated single cells within an epithelial sheet of precursor cells. During the process, each future nerve cell or committed nerve-cell precursor signals to its immediate neighbors not to develop in the same way at the same time, a process known as *lateral inhibition*. In a fly embryo, for example, the inhibited cells around the future nerve-cell precursors develop into epidermal cells. Lateral inhibition depends on a contact-dependent signaling mechanism that is mediated by a signal protein called **Delta**, displayed on the surface of the future neural cell. By binding to Notch on a neighboring cell, Delta signals to the neighbor not to become neural ([Figure 15-70](#)). When this signaling process is defective in flies, the neighbors of neural cells also develop as neural cells, producing a huge excess of neurons at the expense of epidermal cells, which is lethal. Signaling between adjacent cells via Notch and Delta (or the Deltalike ligand *Serrate*) regulates cell fate choices in a wide variety of tissues and animals, helping to create fine-grained patterns of distinct cell types. The Notch-mediated signal can have other effects beside lateral inhibition; in some tissues, for example, it works in the opposite way, causing neighboring cells to behave similarly.

Both Notch and Delta are single-pass transmembrane proteins, and both require proteolytic processing to function. Although it is still unclear why Delta has to be cleaved, the cleavage of Notch is central to how Notch activation alters gene expression in the nucleus. When activated by the binding of Delta on another cell, an intracellular protease cleaves off the cytoplasmic tail of Notch, and the released tail moves into the nucleus to activate the transcription of a set of Notch-response genes. The Notch tail acts by binding to a gene regulatory protein called *CSL* (so named because it is called CBF1 in mammals, Suppressor of Hairless in flies, and Lag-1 in worms); this converts CSL from a transcriptional repressor into a transcriptional activator. The products of the main genes directly activated by Notch signaling are themselves gene regulatory proteins, but with an inhibitory action: they block the expression of genes required for neural differentiation (in the nervous system), and of various other genes in other tissues.

The Notch receptor undergoes three proteolytic cleavages, but only the last two depend on Delta. As part of its normal biosynthesis, a protease called *furin* acts in the Golgi apparatus to cleave the newly synthesized Notch protein in its future extracellular domain. This cleavage converts Notch into a heterodimer, which is then transported to the cell surface as the mature receptor. The binding of Delta to Notch induces a second cleavage in the extracellular domain, mediated by a different protease. A final cleavage quickly follows, cutting free the cytoplasmic tail of the activated receptor ([Figure 15-71](#)).

The cleavage of the Notch tail occurs very close to the plasma membrane, just within the transmembrane segment. In this respect it resembles the cleavage of another, more sinister transmembrane protein—the *β -amyloid precursor protein (APP)*, which is expressed in neurons and is implicated in Alzheimer's disease. APP is cleaved within its transmembrane segment, releasing one peptide fragment into the extracellular space of the brain and another into the

cytosol of the neuron. In Alzheimer's disease, the extracellular fragments accumulate in excessive amounts and aggregate into filaments that form amyloid plaques, which are believed to injure nerve cells and contribute to their loss. The most frequent genetic cause of early-onset Alzheimer's disease is a mutation in the *presenilin-1 (PS-1)* gene, which encodes an 8-pass transmembrane protein that participates in the cleavage of APP. The mutations in PS-1 cause cleavage of APP into amyloid-plaque-forming fragments at an increased rate. Genetic evidence in *C. elegans*, *Drosophila*, and mice indicates that the PS-1 protein is a required component of the Notch signaling pathway, helping to perform the final cleavage that activates Notch. Indeed, Notch signaling and cleavage are greatly impaired in PS-1-deficient cells.

Remarkably, Notch signaling is regulated by glycosylation. The *Fringe* family of glycosyltransferases adds extra sugars to the O-linked oligosaccharide (discussed in [Chapter 13](#)) on Notch, which alters the specificity of Notch for its ligands. This has provided the first example of the modulation of ligand-receptor signaling by differential receptor glycosylation. [↑ TOP](#)

Wnt Proteins Bind to Frizzled Receptors and Inhibit the Degradation of β -Catenin

Wnt proteins are secreted signal molecules that act as local mediators to control many aspects of development in all animals that have been studied. They were discovered independently in flies and in mice: in *Drosophila*, the *wingless (wg)* gene originally came to light because of its role in wing development, while in mice, the *Int-1* gene was found because it promoted the development of breast tumors when activated by the integration of a virus next to it. The cell-surface receptors for the Wnts belong to the **Frizzled** family of seven-pass transmembrane proteins. They resemble G-protein-linked receptors in structure, and some of them can signal through G proteins and the inositol phospholipid pathway discussed earlier. They mainly signal, however, through G-protein-independent pathways, which require a cytoplasmic signaling protein called *Dishevelled*.

The best characterized of the Dishevelled-dependent pathways acts by regulating the proteolysis of a multifunctional protein called **β -catenin** (or Armadillo in flies), which functions both in cell-cell adhesion and as a latent gene regulatory protein. Wnts activate this pathway by binding to both a Frizzled protein and a co-receptor protein. The co-receptor protein is related to the low density lipoprotein (LDL) receptor protein (discussed in [Chapter 13](#)) and is therefore called *LDL-receptor-related protein (LRP)*. It is uncertain how Frizzled and LRP activate Dishevelled, which relays the signal onward.

In the absence of Wnt signaling, most of a cell's β -catenin is located at cell-cell adherens junctions, where it is associated with *cadherins*, which are transmembrane adhesion proteins. As discussed in [Chapter 19](#), the β -catenin in these junctions helps link the cadherins to the actin cytoskeleton. Any β -

catenin not associated with cadherins is rapidly degraded in the cytoplasm. This degradation depends on a large degradation complex, which recruits β -catenin and contains at least three other proteins ([Figure 15-72A](#)):

1. A serine/threonine kinase called **glycogen synthase kinase-3 β** (GSK-3 β) phosphorylates β -catenin, thereby marking the protein for ubiquitylation and rapid degradation in proteasomes.
2. The tumor-suppressor protein **adenomatous polyposis coli (APC)** is so named because the gene encoding it is often mutated in a type of benign tumor (adenoma) of the colon. The tumor projects into the lumen as a polyp, which can eventually become malignant. APC helps promote the degradation of β -catenin by increasing the affinity of the degradation complex for β -catenin, as required for effective phosphorylation of β -catenin by GSK-3 β .
3. A scaffold protein called *axin* holds the protein complex together.

The binding of a Wnt protein to Frizzled and LRP leads to the inhibition of β -catenin phosphorylation and degradation. The mechanism is not understood in detail, but it requires Dishevelled and several other signaling proteins that bind to Dishevelled, including the serine/threonine kinase called *casein kinase 1*. As a result, unphosphorylated β -catenin accumulates in the cytoplasm and nucleus ([Figure 15-72B](#)).

In the nucleus, the target genes for Wnt signaling are normally kept silent by an inhibitory complex of gene regulatory proteins, which includes proteins of the *LEF-1/TCF* family bound to the corepressor protein *Groucho* (see [Figure 15-72A](#)). The increase in undegraded β -catenin caused by Wnt signaling allows β -catenin to enter the nucleus and bind to LEF-1/TCF, displacing Groucho. The β -catenin now functions as a coactivator, inducing the transcription of the Wnt target genes (see [Figure 15-72B](#)).

Among the genes activated by β -catenin is *c-myc*, which encodes a protein (c-Myc) that is a powerful stimulator of cell growth and proliferation (discussed in [Chapter 17](#)). Mutations of the *APC* gene occur in 80% of human colon cancers. These mutations inhibit the protein's ability to bind β -catenin, so that β -catenin accumulates in the nucleus and stimulates the transcription of *c-myc* and other Wnt target genes, even in the absence of Wnt signaling. The resulting uncontrolled cell proliferation promotes the development of cancer. [↑ TOP](#)

Hedgehog Proteins Act Through a Receptor Complex of Patched and Smoothed, Which Oppose Each Other

Like Wnt proteins, the **Hedgehog** proteins are a family of secreted signal

molecules that act as local mediators in many developmental processes in both invertebrates and vertebrates. Abnormalities in the Hedgehog pathway during development can be lethal and in adult cells can also lead to cancer. The Hedgehog proteins were discovered in *Drosophila*, where a mutation in the only gene encoding such a protein produces a larva with spiky processes (denticles) resembling a hedgehog. At least three genes encode Hedgehog proteins in vertebrates—*sonic*, *desert*, and *indian hedgehog*. The active form of all Hedgehog proteins is unusual in that it is covalently coupled to cholesterol, which helps to restrict its diffusion following secretion. The cholesterol is added during a remarkable processing step, in which the protein cleaves itself. The proteins are also modified by the addition of a fatty acid chain, which, for unknown reasons, can be required for their signaling activity.

Two transmembrane proteins, Patched and Smoothed, mediate the responses to all Hedgehog proteins. **Patched** is predicted to cross the plasma membrane 12 times, and it is the receptor that binds the Hedgehog protein. In the absence of a Hedgehog signal, Patched inhibits the activity of **Smoothed**, which is a 7-pass transmembrane protein with a structure similar to a Frizzled protein. This inhibition is relieved when a Hedgehog protein binds to Patched, allowing Smoothed to relay the signal into the cell. Most of what we know about the downstream signaling pathway activated by Smoothed comes from genetic studies in flies, and it is the fly pathway that we summarize here.

In some respects the Hedgehog signaling pathway in *Drosophila* operates similarly to the Wnt pathway. In the absence of a Hedgehog signal, a gene regulatory protein called **Cubitus interruptus (Ci)** is proteolytically cleaved in proteasomes. Instead of being completely degraded, however, it is processed to form a smaller protein that accumulates in the nucleus, where it acts as a transcriptional repressor, helping to keep some Hedgehog-responsive genes silent. The proteolytic processing of the Ci protein depends on a large multiprotein complex. The complex contains a serine/threonine kinase (called Fused) of unknown function, an anchoring protein (called Costal) that binds the complex to microtubules (keeping Ci out of the nucleus), and an adaptor protein (called Suppressor of Fused) ([Figure 15-73A](#)). When Hedgehog binds to Patched to activate the signaling pathway, Ci processing is suppressed, and the unprocessed Ci protein is released from its complex and enters the nucleus, where it activates the transcription of Hedgehog target genes ([Figure 15-73B](#)).

Among the genes activated by Ci is the gene that encodes the Wnt protein Wingless, which helps pattern tissues in the fly embryo (discussed in [Chapter 21](#)). Another target gene is *patched* itself; the resulting increase in Patched protein on the cell surface inhibits further Hedgehog signaling—a form of negative feedback.

Many gaps in the Hedgehog signaling pathway still remain to be filled in. It is not known, for example, how Patched inhibits Smoothed, how Smoothed activates the pathway, how the proteolysis of Ci is regulated (although it is known that Ci phosphorylation by PKA is required for the processing), or how

the release of the complex from microtubules and unprocessed Ci from the complex is controlled.

Even less is known about the Hedgehog pathway in vertebrate cells. In addition to there being at least three types of vertebrate Hedgehog proteins, there are two forms of Patched and three Ci-like proteins (*Gli1*, *Gli2*, and *Gli3*). Unlike in flies, Hedgehog signaling stimulates the transcription of the *Gli* genes, and it is unclear whether all of the *Gli* proteins undergo proteolytic processing, although there is evidence that *Gli3* does. Inactivating mutations in one of the human *patched* genes, which leads to excessive Hedgehog signaling, occur frequently in the most common form of skin cancer (*basal cell carcinoma*), suggesting that Patched normally helps to keep skin cell proliferation in check. [↑ TOP](#)

Multiple Stressful and Proinflammatory Stimuli Act Through an NF- κ B-Dependent Signaling Pathway

The **NF- κ B proteins** are latent gene regulatory proteins that lie at the heart of most inflammatory responses. These responses occur as a reaction to infection or injury and help protect the animal and its cells from these stresses. When excessive or inappropriate, however, inflammatory responses can also damage tissue and cause severe pain, as happens in joints in rheumatoid arthritis, for example. NF- κ B proteins also have an important role in intercellular signaling during normal vertebrate development, although the extracellular signals that activate NF- κ B in these circumstances are unknown. In *Drosophila*, however, genetic studies have identified both the extracellular and the intracellular proteins that activate the NF- κ B family member *Dorsal*, which has a crucial role in specifying the dorsal-ventral axis of the developing fly embryo (discussed in [Chapter 21](#)). The same intracellular signaling pathway is also involved in defending the fly from infection, just as in vertebrates.

Two vertebrate cytokines are especially important in inducing inflammatory responses—*tumor necrosis factor α* (TNF- α) and *interleukin-1* (IL-1). Both are made by cells of the innate immune system, such as macrophages, in response to infection or tissue injury. These proinflammatory cytokines bind to cell-surface receptors and activate NF- κ B, which is normally sequestered in an inactive form in the cytoplasm of almost all of our cells. Once activated, NF- κ B turns on the transcription of more than 60 known genes that participate in inflammatory responses. Although TNF- α receptors and IL-1 receptors are structurally unrelated, they operate in much the same way.

There are five NF- κ B proteins in mammals (RelA, RelB, c-Rel, NF- κ B1, and NF- κ B2), and they form a variety of homodimers and heterodimers, each of which activates its own characteristic set of genes. Inhibitory proteins called **I κ B** bind tightly to the dimers and hold them in an inactive state within large protein complexes in the cytoplasm. Signals such as TNF- α or IL-1 activate

the dimers by triggering a signaling pathway that leads to the phosphorylation, ubiquitylation, and consequent degradation of I κ B. The degradation of I κ B exposes a nuclear localization signal on the NF- κ B proteins, which now move into the nucleus and stimulate the transcription of specific genes. The phosphorylation of I κ B is performed by a specific serine/threonine kinase called **I κ B kinase (IKK)**.

The mechanism by which the binding of a proinflammatory cytokine to its cell-surface receptors activates I κ B kinase is illustrated for the TNF- α receptor in [Figure 15-74](#). Ligand binding causes the cytosolic tails of the clustered receptors to recruit various adaptor proteins and cytoplasmic serine/threonine kinases. One of the recruited kinases is thought to be an *I κ B kinase kinase (IKKK)* that directly phosphorylates and activates the I κ B kinase (IKK).

Not all of the signaling proteins recruited to the cytosolic tail of the TNF- α receptor contribute to NF- κ B activation, however. Some can trigger a MAP-kinase cascade, while others can activate a proteolytic cascade that leads to apoptosis (discussed in [Chapter 17](#)).

Thus far, we have discussed cell signaling mainly in animals, with a few diversions into yeasts and bacteria. But intercellular signaling is just as important for plants as it is for animals, although the mechanisms and molecules used are mainly different, as we discuss next. [↑ TOP](#)

Summary

Some signaling pathways that are especially important in animal development depend on proteolysis for at least part of their action. Notch receptors are activated by cleavage when Delta (or a related ligand) on another cell binds to them; the cleaved cytosolic tail of Notch migrates into the nucleus, where it stimulates gene transcription. In the Wnt signaling pathway, by contrast, the proteolysis of the latent gene regulatory protein β -catenin is inhibited when secreted Wnt proteins bind to their receptors; as a result, β -catenin accumulates in the nucleus and activates the transcription of Wnt target genes.

Hedgehog signaling in flies works much like Wnt signaling: in the absence of a signal, a bifunctional, cytoplasmic gene regulatory protein Ci is proteolytically cleaved to form a transcriptional repressor that keeps Hedgehog target genes silenced. The binding of Hedgehog to its receptor inhibits the proteolytic processing of Ci; as a result, the larger form of Ci accumulates in the nucleus and activates the transcription of Hedgehog-responsive genes. Signaling through the latent gene regulatory protein NF- κ B also depends on proteolysis. NF- κ B is normally held in an inactive state by the inhibitory protein I κ B within a multiprotein complex in the cytoplasm. A variety of extracellular stimuli, including proinflammatory cytokines, trigger a phosphorylation cascade that ultimately phosphorylates I κ B, marking it for

degradation; this enables the freed NF- κ B to enter the nucleus and activate the transcription of its target genes. [↑ TOP](#)

Figure 15-70. Lateral inhibition mediated by Notch and Delta during nerve cell development in *Drosophila*. When individual cells in the epithelium begin to develop as neural cells, they signal to their neighbors not to do the same. This inhibitory, contact-dependent signaling is mediated by the ligand Delta that appears on the surface of the future nerve cell and binds to Notch proteins on the neighboring cells. In many tissues, all the cells in a cluster initially express Delta and Notch, and a competition occurs, with one cell emerging as winner, expressing Delta strongly and inhibiting its neighbors from doing likewise. In other cases, additional factors interact with Delta or Notch to make some cells susceptible to the lateral inhibition signal and others deaf to it.

Figure 15-71. The processing and activation of Notch by proteolytic cleavage. The numbered red arrowheads indicate the sites of proteolytic cleavage. The first proteolytic processing step occurs within the *trans* Golgi network to generate the mature heterodimeric Notch receptor that is then displayed on the cell surface. The binding of Delta, which is displayed on a neighboring cell, triggers the next two proteolytic steps. Note that Notch and Delta interact through their repeated EGF-like domains. Some evidence suggests that the tension exerted on Notch by the endocytic machinery of the interacting cells triggers the cleavage at site 2.

Figure 15-72. A model for the Wnt activation of the β -catenin signaling pathway. (A) In the absence of a Wnt signal, some β -catenin is bound to the cytosolic tail of cadherin proteins (not shown) and any cytosolic β -catenin becomes bound by the APC-axin-GSK-3 β degradation complex. In this complex, β -catenin is phosphorylated by GSK-3 β , triggering its ubiquitylation and degradation in proteasomes. Wnt-responsive genes are kept inactive by the Groucho corepressor protein bound to the gene regulatory protein LEF-1/TCF. (B) Wnt binding to Frizzled and LRP activates Dishevelled by an unknown mechanism. By an equally mysterious mechanism, which requires casein kinase 1 (not shown), this leads to the inactivation of GSK-3 β in the degradation complex. As a result, the phosphorylation and degradation of β -catenin is inhibited, and β -catenin accumulates in the

Figure 15-73. A model for Hedgehog signaling in *Drosophila*. (A) In the absence of Hedgehog, the Patched receptor inhibits Smoothed probably by promoting the degradation or intracellular sequestration of Smoothed. The Ci protein is located in a protein complex and is cleaved to form a transcriptional repressor, which accumulates in the nucleus to help keep Hedgehog target genes inactive. The protein complex includes the serine/threonine kinase Fused, the anchoring protein Costal (which binds the complex to microtubules), and the adaptor protein Suppressor of Fused. (B) Hedgehog binding to Patched relieves the inhibition of Smoothed, which

Figure 15-74. The activation of NF- κ B by TNF- α . Both TNF- α and its receptors are trimers. The binding of TNF- α causes a rearrangement of the clustered cytosolic tails of the receptors, which now recruit a number of intracellular signaling proteins, including the *receptor-interacting protein kinase* (RIP) and two adaptor proteins, *TNF-associated death-domain protein* (TRADD) and *TNF-receptor-associated factor 2* (TRAF2). These then recruit and activate an unidentified kinase, I κ B kinase kinase kinase (IKKK), which phosphorylates and activates I κ B kinase kinase (IKK). IKK is a heterotrimer composed of two kinase subunits (IKK- α and IKK- β) and a regulatory adaptor subunit called IKK- γ . The IKK- β then phosphorylates I κ B on two serines, which marks the protein for ubiquitylation and degradation

in proteasomes. The nuclear localization signal on the free NF- κ B now directs the transport of this protein into the nucleus where, in collaboration with coactivator proteins, it stimulates the transcription of its target genes. In addition to target genes involved in the inflammatory response, NF- κ B also activates the *I κ B* gene, providing negative feedback (not shown). The role of RIP is unclear: although it is required for TNF signaling, its kinase domain is not.

Signaling in Plants

In plants, as in animals, cells are in constant communication with one another. Plant cells communicate to coordinate their activities in response to the changing conditions of light, dark, and temperature that guide the plant's cycle of growth, flowering, and fruiting. Plant cells also communicate to coordinate what goes on in their roots, stems, and leaves. In this final section, we consider how plant cells signal to one another and how they respond to light. Much less is known about the receptors and intracellular signaling mechanisms involved in cell communication in plants, and we shall concentrate mainly on how these differ from those used by animals. We discuss some of the details of plant development in [Chapter 21](#).

Multicellularity and Cell Communication Evolved Independently in Plants and Animals

Although plants and animals are both eucaryotes, they have had separate evolutionary histories for more than a billion years. Their last common ancestor was a unicellular eucaryote that had mitochondria but no chloroplasts. The plant lineage acquired chloroplasts after plants and animals diverged. The earliest fossils of multicellular animals and plants date from almost 600 million years ago. Thus, it seems that plants and animals evolved multicellularity independently, each starting from a different unicellular eucaryote, sometime between 1.6 and 0.6 billion years ago ([Figure 15-75](#)).

If multicellularity evolved independently in plants and animals, the molecules and mechanisms used for cell communication will have evolved separately and would be expected to be different. Some degree of resemblance is expected, however, as both plant and animal genes diverged from the set of genes contained by the unicellular eucaryote that was the last common ancestor of plants and animals. Nitric oxide and Ca^{2+} are widely used for signaling in both plants and animals. However, because the genome of *Arabidopsis thaliana*, a widely studied small flowering plant, has been completely sequenced, we know that there are no homologs of Wnt, Hedgehog, Notch, Jak/STAT, TGF- β , Ras, or the nuclear receptor family in this organism. Similarly, cyclic AMP has not been definitively implicated in intracellular signaling in plants,

although cyclic GMP has.

Much of what is known about the molecular mechanisms involved in signaling in plants has come from genetic studies on *Arabidopsis*. Although the specific molecules used in cell communication in plants often differ from those used in animals, the general strategies are frequently very similar. Enzyme-linked cell-surface receptors, for example, are used in both lineages, as we now discuss. [↑ TOP](#)

Receptor Serine/Threonine Kinases Function as Cell-Surface Receptors in Plants

Like animals, plants make extensive use of cell-surface receptors. Whereas most cell-surface receptors in animals are G-protein-linked, most found so far in plants are enzyme-linked. Moreover, whereas the largest class of enzyme-linked receptors in animals is receptor tyrosine kinases, this type of receptor is extremely rare in plants, even though they contain many cytoplasmic tyrosine kinases, and tyrosine phosphorylation and dephosphorylation have important roles in plant cell signaling. Instead, plants seem to rely on a great diversity of transmembrane *receptor serine/threonine kinases*, which are distinct from this type of receptor used by animal cells. Like the animal receptors, however, they have a typical serine/threonine kinase cytoplasmic domain and an extracellular ligand-binding domain. The most abundant types identified so far have a tandem array of extracellular leucine-rich repeats ([Figure 15-76](#)) and are therefore called **leucine-rich repeat (LRR) proteins**.

There are about 80 LRR receptor kinases encoded by the *Arabidopsis* genome. One of the best-studied examples is **CLAVATA 1 (CLV1)**, which was originally identified in genetic studies. Mutations that inactivate the protein cause the production of flowers with extra floral organs and a progressive enlargement of both the shoot and floral *meristems*, which are groups of self-renewing stem cells producing the cells that give rise to stems, leaves, and flowers (discussed in [Chapter 21](#)). The extracellular signal molecule for the receptor is thought to be a small protein called CLV3, which is secreted by neighboring cells. The binding of CLV3 to its receptor, CLV1, suppresses meristem growth, either by inhibiting cell division there or, more probably, by stimulating cell differentiation ([Figure 15-77A](#)). The intracellular signaling pathway from CLV1 to the cell response is largely unknown, but it includes a serine/threonine protein phosphatase that inhibits CLV1 signaling; also involved is a small GTP-binding protein of the Rho class and a nuclear gene regulatory protein that is distantly related to homeodomain proteins. Mutations that inactivate this gene regulatory protein have the opposite effect of mutations that inactivate CLV1: cell division is greatly decreased in the shoot meristem, and the plant produces flowers with too few organs. Thus, the intracellular signaling pathway activated by CLV1 is thought to normally stimulate cell differentiation by inhibiting the gene regulatory protein that normally inhibits cell differentiation ([Figure 15-77B](#)).

A different LRR receptor kinase called *BRI1* acts as a cell-surface steroid hormone receptor in *Arabidopsis*. Plants synthesize a class of steroids called *brassinosteroids*, because they were originally identified in the mustard family Brassicaceae, which includes *Arabidopsis*. During development, these plant growth regulators stimulate cell expansion and help mediate responses to darkness. Mutant plants that are deficient in the BRI1 receptor kinase are insensitive to brassinosteroids. Normally, *Arabidopsis* plants grown in darkness are white and gangly as a result of brassinosteroid signaling; in the absence of brassinosteroid signaling, they become green, as though they were growing in light, and the mature plant is severely dwarfed. As for the other known LRR receptor kinases in plants, the nature of the signal transduction pathway that leads from the receptor to the response remains a mystery.

The LRR receptor kinases are only one of many classes of transmembrane receptor serine/threonine kinases in plants. There are at least six additional families, each with its own characteristic set of extracellular domains. The *lectin receptor kinases*, for example, have extracellular domains that bind carbohydrate signal molecules. The *Arabidopsis* genome encodes over 300 receptor serine/threonine kinases, which makes this family of receptors the largest one known in plants. Many of these are involved in defense responses against pathogens.  [TOP](#)

Ethylene Activates a Two-Component Signaling Pathway

Various **growth regulators** (also called *plant hormones*) help to coordinate plant development. They include *ethylene*, *auxin*, *cytokinins*, *gibberellins*, and *abscisic acid*. Growth regulators are all small molecules made by most plant cells. They diffuse readily through cell walls and they can act locally or be transported to influence cells further away. Each growth regulator can have multiple effects. The specific effect depends on which other growth regulators are acting, on environmental conditions, on the nutritional state of the plant, and on the responsiveness of the target cell.

Ethylene is an important example. This small gas molecule can influence plant development in various ways, including the promotion of fruit ripening, leaf abscission, and plant senescence. It also functions as a stress signal in response to wounding, infection, flooding, and so on. When the shoot of a germinating seedling, for example, encounters an obstacle, such as a piece of gravel underground in the soil, the seedling responds to the encounter in three ways. First, it thickens its stem, which can then exert more force on the obstacle. Second, it shields the tip of the shoot by increasing the curvature of a specialized hook structure. Third, it reduces the shoot's tendency to grow away from the direction of gravity to avoid the obstacle. This "triple response" is controlled by ethylene ([Figure 15-78C, D](#)).

Plants have a number of ethylene receptors, which are all structurally related. They are dimeric transmembrane proteins that are thought to function as

histidine kinases. Ethylene receptors have an extracellular domain, which contains a copper atom that binds ethylene, and an intracellular histidine-kinase-like domain. In a manner similar to the two-component signaling pathway involved in bacterial chemotaxis discussed earlier, the kinase domain, when active, phosphorylates itself on histidine and then is believed to transfer the phosphate to an aspartic acid in another domain of the receptor. In bacterial chemotaxis, the binding of an attractant inactivates the receptor. Similarly, the binding of ethylene inactivates ethylene receptors, inhibiting the kinase domain and the downstream signaling pathway emanating from it. In its unbound, active state, the receptor activates the first component of a MAP-kinase signaling module (see [Figure 15-56](#)). The activation of this MAP-kinase cascade leads to the *inactivation* of gene regulatory proteins in the nucleus that are responsible for stimulating the transcription of ethylene-responsive genes. The binding of ethylene to the receptors inactivates this signaling pathway, thereby turning these genes on ([Figure 15-78A, B](#)).

Two-component signaling systems operate in bacteria and fungi, as well as in plants, but apparently not in animals. Why animals should have given up this way of signaling remains a mystery.

Plant development is greatly influenced by environmental conditions. Unlike animals, plants cannot move on when conditions become unfavorable; they have to adapt, or they die. The most important environmental influence is light, which is their energy source and has a major role throughout their entire life cycle—from germination, through seedling development, to flowering and senescence. Plants have evolved a large set of light-sensitive proteins to monitor the quantity, quality, direction, and duration of light, as we now discuss. [↑ TOP](#)

Phytochromes Detect Red Light, and Cryptochromes Detect Blue Light

Both plants and animals use a variety of light-responsive proteins to sense light of different wavelengths. In plants, these are usually referred to as *photoreceptors*. However, because the term photoreceptor is also used for light-sensitive cells in the animal retina (see p. 867), we shall use the term *photoprotein* instead. All photoproteins sense light by means of a covalently attached light-absorbing chromophore, which changes its shape in response to light and then induces a change in the protein's conformation. Animals use some of the same photoprotein families used by plants. The most extensively studied animal photoproteins are the rhodopsins, which are membrane-bound, G-protein-linked proteins that regulate ion channels in the light-sensitive cells of the retina, as discussed earlier.

The best-known plant photoproteins are the **phytochromes**, which are present in all plants and in some algae. These are dimeric, cytoplasmic serine/threonine kinases that respond differentially and reversibly to red and far-red

light: whereas red light usually activates the kinase activity of the phytochrome, far-red light inactivates it. When activated by red light, the phytochrome is thought to phosphorylate itself and then to phosphorylate one or more other proteins in the cell. In some light responses, the activated phytochrome migrates into the nucleus, where it interacts with gene regulatory proteins to alter gene transcription ([Figure 15-79](#)). In other cases, the activated phytochrome activates a gene regulatory protein in the cytoplasm, which then migrates into the nucleus to regulate gene transcription. In still other cases, the photoprotein triggers signaling pathways in the cytosol that alter the cell's behavior without involving the nucleus.

Although the phytochromes possess serine/threonine kinase activity, parts of their structure resemble the histidine kinases involved in bacterial chemotaxis. This finding suggests that the plant phytochromes originally descended from bacterial histidine kinases and only later in evolution altered their substrate specificity from histidine to serine and threonine.

Plants sense blue light using two types of photoproteins, phototropin and cryptochromes. **Phototropin** is associated with the plasma membrane and is partly responsible for *phototropism*, the tendency of plants to grow toward light. Phototropism occurs by directional cell elongation, which is stimulated by the growth regulator auxin, but the links between phototropin and auxin are unknown.

Cryptochromes are flavoproteins that are sensitive to blue light. They are structurally related to blue-light-sensitive enzymes called *photolyases*, which are involved in the repair of ultraviolet-induced DNA damage in all organisms, except most mammals. Unlike phytochromes, cryptochromes are also found in animals, where they have an important role in circadian clocks that operate in most cells and cycle with a 24-hour rhythm (discussed in [Chapter 7](#)). The cryptochromes do not have a DNA repair activity, but they are thought to have evolved from the photolyases.

In this chapter, we have discussed how extracellular signals can influence cell behavior. One crucial intracellular target of these signals is the cytoskeleton, which determines cell shape and is responsible for cell movements, as we discuss in the next chapter. [↑ TOP](#)

Summary

Plants and animals are thought to have evolved multicellularity and cell communication mechanisms independently, each starting from a different unicellular eucaryote, which in turn evolved from a common unicellular eucaryotic ancestor. Not surprisingly, therefore, the mechanisms of signaling between cells in animals and plants have both similarities and differences. Whereas animals rely mainly on G-protein-linked surface receptors, for example, plants rely mainly on enzyme-linked receptors of the receptor serine/

threonine type, especially ones with extracellular leucine-rich repeats. A number of growth regulators, including ethylene, help coordinate plant development. Ethylene acts through receptor histidine kinases in a two-component signaling pathway that resembles the pathway used in bacterial chemotaxis. Light has an important role in regulating plant development. These light responses are mediated by a variety of light-sensitive photoproteins, including phytochromes, which are responsive to red light, and cryptochromes and phototropin, which are sensitive to blue light. Signaling in Plants

Figure 15-77. A hypothetical model for CLV1 receptor serine/threonine kinase regulation of cell proliferation and/or differentiation in the shoot meristem. (A) Cells in the outer layer of the meristem secrete CLV3 protein, which binds to CLV1 receptor proteins on target cells in an adjacent, more central region of the meristem, presumably stimulating the differentiation of the target cells. (B) Some parts of the intracellular signaling pathway activated by CLV3 binding. The CLV receptor protein is thought to be a homodimer or heterodimer, which phosphorylates itself on serines and threonines, thereby activating the receptor and leading to the activation of a Rho-like GTPase. The signaling pathway after this point is unclear, but it leads to the inhibition of a gene regulatory protein in the nucleus, thereby blocking the transcription of genes that otherwise might inhibit differentiation. The phosphatase dephosphorylates the receptor and thereby negatively regulates the signaling pathway.

16. The Cytoskeleton

Cells have to organize themselves in space and interact mechanically with their environment. They have to be correctly shaped, physically robust, and properly structured internally. Many of them also have to be able to change their shape and move from place to place. All of them have to be able to rearrange their internal components as they grow, divide, and adapt to changing circumstances. All these spatial and mechanical functions are developed to a very high degree in eucaryotic cells, where they depend on a remarkable system of filaments called the cytoskeleton (Figure 16-1).

The cytoskeleton pulls the chromosomes apart at mitosis and then splits the dividing cell into two. It drives and guides the intracellular traffic of organelles, ferrying materials from one part of the cell to another. It supports the fragile plasma membrane and provides the mechanical linkages that let the cell bear stresses and strains without being ripped apart as the environment shifts and changes. It enables some cells, such as sperm, to swim, and others, such as fibroblasts and white blood cells, to crawl across surfaces. It provides the machinery in the muscle cell for contraction and in the neuron to extend an axon and dendrites. It guides the growth of the plant cell wall and controls the amazing diversity of eucaryotic cell shapes.

The varied functions of the cytoskeleton center on the behavior of three families of protein molecules, which assemble to form three main types of filaments. Each type of filament has distinct mechanical properties and dynamics, but certain fundamental principles are common to them all. These principles provide the basis for a general understanding of how the cytoskeleton works.

In this chapter, we begin by describing the three main types of filaments, the basic principles underlying their assembly and disassembly, and their individual peculiarities. We then describe how other proteins interact with the three main filament systems, enabling the cell to establish and maintain internal order, to shape and remodel its surface, to move organelles in a directed manner from one place to another, and—when appropriate—to move itself to new locations. The wonderfully coordinated actions of the cytoskeleton in cell division are discussed separately, in [Chapter 18](#). [↑ TOP](#)

The Self-Assembly and Dynamic Structure of Cytoskeletal Filaments

Three types of cytoskeletal filaments are common to many eucaryotic cells and are fundamental to the spatial organization of these cells. *Intermediate filaments* provide mechanical strength and resistance to shear stress.

Microtubules determine the positions of membrane-enclosed organelles and direct intracellular transport. *Actin filaments* determine the shape of the cell's surface and are necessary for whole-cell locomotion ([Panel 16-1](#)). But these cytoskeletal filaments would be ineffective on their own. Their usefulness to the cell depends on a large number of accessory proteins that link the filaments to other cell components, as well as to each other. This set of *accessory proteins* is essential for the controlled assembly of the cytoskeletal filaments in particular locations, and it includes the *motor proteins* that either move organelles along the filaments or move the filaments themselves.

Cytoskeletal systems are dynamic and adaptable, organized more like ant trails than interstate highways. A single trail of ants may persist for many hours, extending from the ant nest to a delectable picnic site, but the individual ants within the trail are anything but static. If the ant scouts find a new and better source of food, or if the picnickers clean up and leave, the dynamic structure rearranges itself with astonishing rapidity, to deal with the new situation. In a similar way, large-scale cytoskeletal structures can change or persist, according to need, lasting for lengths of time ranging from less than a minute up to the lifetime of the cell. The individual macromolecular components that make up these structures are in a constant state of flux. Thus, like the alteration of an ant trail, a structural rearrangement in a cell requires little extra energy when conditions change. In this section, we discuss the remarkable mechanisms that cause cytoskeletal filaments to be dynamic, and thereby able to respond rapidly to any eventuality.

Regulation of the dynamic behavior and assembly of the cytoskeletal filaments allows eucaryotic cells to build an enormous range of structures from the three basic filament systems. Micrographs that reveal some of these structures are shown in [Panel 16-1](#). Microtubules, which are frequently found in a star-like cytoplasmic array emanating from the center of an interphase cell, can quickly

rearrange themselves to form a bipolar *mitotic spindle* during cell division. They can also form motile whips called *cilia* and *flagella* on the surface of the cell, or tightly aligned bundles that serve as tracks for the transport of materials down long neuronal axons. Actin filaments form many types of cell-surface projections. Some of these are dynamic structures, such as the *lamellipodia* and *filopodia* that cells use to explore territory and pull themselves around. Others are stable structures such as the regular bundles of *stereocilia* on the surface of hair cells in the inner ear, which tilt as rigid rods in response to sound. Inside cells, actin filaments can also form either transient or stable structures: the *contractile ring*, for example, assembles transiently to divide cells in two during cytokinesis; more stable arrays allow cells to brace themselves against an underlying substratum and enable muscle to contract. Intermediate filaments line the inner face of the nuclear envelope, forming a protective cage for the cell's DNA; in the cytosol, they are twisted into strong cables that can hold epithelial cell sheets together, help neuronal cells to extend long and robust axons, or allow us to form tough appendages such as hair and fingernails.

Each Type of Cytoskeletal Filament Is Constructed from Smaller Protein Subunits

Cytoskeletal structures frequently reach all the way from one end of the cell to the other, spanning tens or even hundreds of micrometers. Yet the individual protein molecules of the cytoskeleton are generally only a few nanometers in size. The cell is able to build the large structures by the repetitive assembly of large numbers of the small subunits, like building a skyscraper out of bricks. Because these subunits are small, they can diffuse rapidly within cytoplasm, whereas the assembled filaments cannot. In this way, cells can undergo rapid structural reorganizations, disassembling filaments at one site and reassembling them at another site far away ([Figure 16-2](#)).

Intermediate filaments are made up of smaller subunits that are themselves elongated and fibrous, whereas actin filaments and microtubules are made of subunits that are compact and globular—*actin subunits* for actin filaments, *tubulin subunits* for microtubules. All three types of cytoskeletal filaments form as helical assemblies of subunits (see [Figure 3-27](#)), which self-associate, using a combination of end-to-end and side-to-side protein contacts. Differences in the structures of the subunits and the strengths of the attractive forces between them produce critical differences in the stability and mechanical properties of each type of filament.

Many biological polymers—including DNA, RNA, and proteins—are held together by covalent linkages between their subunits. In contrast, the three types of cytoskeletal "polymers" are held together by weak noncovalent interactions, which means that their assembly and disassembly can occur rapidly, without covalent bonds being formed or broken.

Within the cell, hundreds of different cytoskeleton-associated accessory proteins regulate the spatial distribution and the dynamic behavior of the filaments. These accessory proteins bind to the filaments or their subunits to determine the sites of assembly of new filaments, to regulate the partitioning of polymer proteins between filament and subunit forms, to change the kinetics of filament assembly and disassembly, to harness energy to generate force, and to link filaments to one another or to other cellular structures such as organelles and the plasma membrane. In these processes, the accessory proteins bring cytoskeletal structure under the control of extracellular and intracellular signals, including those that trigger the dramatic transformations of the cytoskeleton that occur during the cell cycle. Acting together, the accessory proteins enable a eucaryotic cell to maintain a highly organized but flexible internal structure and, in many cases, to move.  [TOP](#)

Filaments Formed from Multiple Protofilaments Have Advantageous Properties

In general, the linking of protein subunits together to form a filament can be thought of as a simple association reaction. A free subunit binds to the end of a filament that contains n subunits to generate a filament of length $n + 1$. The addition of each subunit to the end of the polymer creates a new end to which yet another subunit can bind. However, the robust cytoskeletal filaments in living cells are not built by simply stringing subunits together in this way in a single straight file. A thousand tubulin monomers, for example, lined up end to end, would be enough to span the diameter of a small eucaryotic cell, but a filament formed in this way would not have enough strength to avoid breakage by ambient thermal energy, unless each subunit were bound very tightly to its neighbor. Such tight binding would limit the rate at which the filaments could disassemble, making the cytoskeleton a static and less useful structure.

Cytoskeletal polymers combine strength with adaptability because they are built out of multiple protofilaments—long linear strings of subunits joined end to end—that associate with one another laterally. Typically, the protofilaments twist around one another in a helical lattice. The addition or loss of a subunit at the end of one protofilament makes or breaks one set of longitudinal bonds and either one or two sets of lateral bonds. In contrast, breakage of the composite filament in the middle requires breaking sets of longitudinal bonds in several protofilaments all at the same time ([Figure 16-3](#)). The large energy difference between these two processes allows most cytoskeletal filaments to resist thermal breakage, while leaving the filament ends as dynamic structures in which addition and loss of subunits occur rapidly.

As with other specific protein-protein interactions, the subunits in a cytoskeletal filament are held together by a large number of hydrophobic interactions and weak noncovalent bonds (see [Figure 3-5](#)). The locations and types of subunit-subunit contacts are different for the different cytoskeletal filaments. Intermediate filaments, for example, assemble by forming strong

lateral contacts between α -helical coiled coils, which extend over most of the length of each elongated fibrous subunit. Because the individual subunits are staggered in the filament, intermediate filaments tolerate stretching and bending, forming strong rope-like structures ([Figure 16-4](#)). Microtubules, by contrast, are built from globular subunits held together primarily by longitudinal bonds, and the lateral bonds holding the 13 protofilaments together are comparatively weak. For this reason, microtubules break much more easily than do intermediate filaments. [↑ TOP](#)

Nucleation Is the Rate-limiting Step in the Formation of a Cytoskeletal Polymer

There is an important additional consequence of the multiple-protofilament organization of cytoskeletal polymers. Short oligomers composed of a few subunits can assemble spontaneously, but they are unstable and disassemble readily because each monomer is bonded only to a few other monomers. For a new large filament to form, subunits must assemble into an initial aggregate, or nucleus, that is stabilized by many subunit-subunit contacts and can then elongate rapidly by addition of more subunits. The initial process of nucleus assembly is called filament *nucleation*, and it can take quite a long time, depending on how many subunits must come together to form the nucleus. The instability of smaller aggregates creates a kinetic barrier to nucleation, which is easily observed in a solution of pure actin or tubulin—the subunits of actin filaments and microtubules, respectively. When polymerization is initiated in a test tube containing a solution of pure individual subunits (by raising the temperature or raising the salt concentration), there is an initial lag phase, during which no filaments are observed. During this lag phase, however, nuclei are assembling slowly, so that the lag phase is followed by a phase of rapid filament elongation, during which subunits add quickly onto the ends of the nucleated filaments ([Figure 16-5A](#)). Finally, the system approaches a steady state at which the rate of addition of new subunits to the filament ends is exactly balanced by the rate of subunit dissociation from the ends. The concentration of free subunits left in solution at this point is called the *critical concentration*, C_c . As explained in [Panel 16-2](#), the value of the critical concentration is equal to the rate constant for subunit loss divided by the rate constant for subunit addition—that is, $C_c = k_{\text{off}}/k_{\text{on}}$.

The lag phase in filament growth is eliminated if preexisting nuclei (such as filament fragments that have been chemically cross-linked) are added to the solution at the beginning of the polymerization reaction ([Figure 16-5B](#)). The cell takes great advantage of this nucleation requirement: it uses special proteins to catalyze filament nucleation at specific sites, thereby determining the location where new cytoskeletal filaments are assembled. Indeed, this type of regulation of filament nucleation is a primary way that cells control their shape and movement. [↑ TOP](#)

The Tubulin and Actin Subunits Assemble Head-to-Tail, Creating Filaments that Are Polar

Microtubules are formed from protein subunits of tubulin. The tubulin subunit is itself a heterodimer formed from two closely related globular proteins called α -tubulin and β -tubulin, tightly bound together by noncovalent bonds (Figure 16-6). These two tubulin proteins are found only in this complex. Each α or β monomer has a binding site for one molecule of GTP. The GTP that is bound to the α -tubulin monomer is physically trapped at the dimer interface and is never hydrolyzed or exchanged; it can therefore be considered to be an integral part of the tubulin heterodimer structure. The nucleotide on the β -tubulin, in contrast, may be in either the GTP or the GDP form, and it is exchangeable. As we see, the hydrolysis of GTP at this site to produce GDP has an important effect on microtubule dynamics.

A microtubule is a stiff, hollow cylindrical structure built from 13 parallel protofilaments, each composed of alternating α -tubulin and β -tubulin molecules. When the tubulin heterodimers assemble to form the hollow cylindrical microtubule, they generate two new types of protein-protein contacts. Along the longitudinal axis of the microtubule, the "top" of one β -tubulin molecule forms an interface with the "bottom" of the α -tubulin molecule in the adjacent dimer subunit. This interface is very similar to the interface holding the α and β monomers together in the dimer subunit, and the binding energy is strong. Perpendicular to these interactions, lateral contacts are formed between neighboring protofilaments. In this dimension, the main lateral contacts are between monomers of the same type (α - α and β - β). Together, the longitudinal and lateral contacts are repeated in the regular helical lattice of the microtubule. Because most of the subunits in a microtubule are held in place by multiple contacts within the lattice, the addition and loss of subunits occurs almost exclusively at the microtubule ends (see Figure 16-3).

Each protofilament in a microtubule is assembled from subunits that all point in the same direction, and the protofilaments themselves are aligned in parallel (in Figure 16-6, for example, the α -tubulin is down and the β -tubulin up in each heterodimer). Therefore, the microtubule itself has a distinct structural polarity, with α -tubulins exposed at one end and β -tubulins exposed at the other end.

The actin subunit is a single globular polypeptide chain and is thus a monomer rather than a dimer. Like tubulin, each actin subunit has a binding site for a nucleotide, but for actin the nucleotide is ATP (or ADP) rather than GTP (or GDP) (Figure 16-7). As for tubulin, the actin subunits assemble head-to-tail to generate filaments with a distinct structural polarity. The actin filament can be considered to consist of two parallel protofilaments that twist around each other in a right-handed helix. Actin filaments are relatively flexible compared

with the hollow cylindrical microtubules. But in a living cell, actin filaments are cross-linked and bundled together by a variety of accessory proteins (see below), making these large-scale actin structures much stronger than an individual actin filament. [↑ TOP](#)

The Two Ends of a Microtubule and of an Actin Filament Are Distinct and Grow at Different Rates

The structural polarity of actin filaments and microtubules is created by the regular, parallel orientation of all of their subunits. This orientation makes the two ends of each polymer different in ways that have a profound effect on filament growth rates. Addition of a subunit to either end of a filament of n subunits results in a filament of $n + 1$ subunits. In the absence of ATP or GTP hydrolysis, the free energy difference, and therefore the equilibrium constant (and the critical concentration), must be the same for addition of subunits at either end of the polymer. In this case, the ratio of the forward and backward rate constants, $k_{\text{on}}/k_{\text{off}}$, must be identical at the two ends, even though the absolute values of these rate constants may be very different at each end.

In a structurally polar filament, the kinetic rate constants for association and dissociation— k_{on} and k_{off} , respectively—are often much greater at one end than at the other. Thus, if an excess of purified subunits is allowed to assemble onto marked fragments of preformed filaments, one end of each fragment elongates much faster than the other ([Figure 16-8](#)). If filaments are rapidly diluted so that the free subunit concentration drops below the critical concentration, the fast-growing end also depolymerizes fastest. The more dynamic of the two ends of a filament, where both growth and shrinkage are fast, is called the plus end, and the other end is called the minus end.

On microtubules, α subunits are exposed at the minus end, and β subunits are exposed at the plus end. On actin filaments, the ATP-binding cleft on the monomer points toward the minus end. (For historical reasons, the plus ends of actin filaments are usually referred to as "barbed" ends, and minus ends as "pointed" ends, because of the arrowhead appearance of myosin heads when bound along the filament.)

Filament elongation proceeds spontaneously when the free energy change (ΔG) for addition of the soluble subunit is less than zero. This is the case when the concentration of subunits in solution exceeds the critical concentration. Likewise, filament depolymerization proceeds spontaneously when this free energy change is greater than zero. A cell can couple an energetically unfavorable process to these spontaneous processes; thus, the free energy released during spontaneous filament polymerization or depolymerization can be used to do mechanical work—in particular, to push or pull an attached load. For example, elongating microtubules can help push out membranes, and shrinking microtubules can help pull mitotic chromosomes away from their

sisters during anaphase. Similarly, elongating actin filaments help protrude the leading edge of motile cells, as we discuss later. [↑ TOP](#)

Filament Treadmilling and Dynamic Instability Are Consequences of Nucleotide Hydrolysis by Tubulin and Actin

Thus far, our discussion of filament dynamics has ignored a critical fact that applies to both actin filaments and microtubules. In addition to their ability to form noncovalent polymers, the actin and tubulin subunits are both enzymes that can catalyze the hydrolysis of a nucleoside triphosphate, ATP or GTP, respectively. For the free subunits, this hydrolysis proceeds very slowly; however, it is accelerated when the subunits are incorporated into filaments. Shortly after incorporation of an actin or tubulin subunit into a filament, nucleotide hydrolysis occurs; the free phosphate group is released from each subunit, but the nucleoside diphosphate remains trapped in the filament structure. (On tubulin, the nucleotide-binding site lies at the interface between two neighboring subunits—see [Figure 16-6](#), whereas in actin, the nucleotide is deep in a cleft near the center of the subunit—see [Figure 16-7](#).) Thus, two different types of filament structures can exist, one with the "T form" of the nucleotide bound (ATP for actin, GTP for tubulin), and one with the "D form" bound (ADP for actin, GDP for tubulin).

When the nucleotide is hydrolyzed, much of the free energy released by cleavage of the high-energy phosphate-phosphate bond is stored in the polymer lattice, making the free energy change upon dissociation of the D-form polymer higher than the free energy change upon dissociation of the T-form polymer. Consequently, the equilibrium constant for dissociation $K_D = k_{\text{off}}/k_{\text{on}}$ for the D-form polymer, which is numerically equal to its critical concentration $[C_c(D)]$, is larger than the corresponding equilibrium constant for the T-form polymer. Thus, $C_c(D)$ is greater than $C_c(T)$. For certain concentrations of free subunits, D-form polymers will therefore shrink while T-form polymers grow.

In living cells, most of the free subunits are in the T form, as the free concentration of both ATP and GTP is much higher than that of ADP and GDP. The longer the time that subunits have been in the polymer lattice, the more likely they are to have hydrolyzed their bound nucleotide. Whether the subunit at the very end of a filament is in the T or the D form will depend on the relative rates of hydrolysis and subunit addition. If the rate of subunit addition is high, that is if the filament is growing rapidly, then it is likely that a new subunit will add on to the polymer before the nucleotide in the previously added subunit has been hydrolyzed, so that the tip of the polymer remains in the T form, forming an *ATP cap* or *GTP cap*. However, if the rate of subunit addition is low, hydrolysis may occur before the next subunit is added, and the

tip of the filament will then be in the D form.

The rate of subunit addition at the end of a filament is the product of the free subunit concentration and the rate constant k_{on} . The k_{on} is much faster for the plus end of a filament than for the minus end because of a structural difference between the two ends (see [Panel 16-2](#), pp. 912–913). At an intermediate concentration of free subunits, it is therefore possible for the rate of subunit addition to be faster than nucleotide hydrolysis at the plus end, but slower than nucleotide hydrolysis at the minus end. In this case, the plus end of the filament remains in the T conformation, while the minus end adopts the D conformation. As just explained, the D form has a higher critical concentration than the T form; in other words, the D form leans more readily toward disassembly, while the T form leans more readily toward assembly. If the concentration of free subunits in solution is in an intermediate range—higher than the critical concentration of the T form (that is, the plus end), but lower than the critical concentration of the D form (that is, the minus end)—the filament adds subunits at the plus end, and simultaneously loses subunits from the minus end. This leads to the remarkable property of filament treadmilling ([Figure 16-9](#) and [Panel 16-2](#)).

During treadmilling, subunits are recruited at the plus end of the polymer in the T form and shed from the minus end in the D form. The ATP or GTP hydrolysis that occurs along the way gives rise to the difference in the free energy of the association/dissociation reactions at the plus and minus ends of the actin filament or microtubule and thereby makes treadmilling possible. At a particular intermediate subunit concentration, the filament growth at the plus end is exactly balanced by the filament shrinkage at the minus end. Now, the subunits cycle rapidly between the free and filamentous states, while the total length of the filament remains unchanged. This "steady-state treadmilling" requires a constant consumption of energy in the form of nucleoside triphosphate hydrolysis. While the extent of treadmilling inside the cell is uncertain, the treadmilling of single filaments has been observed *in vitro* for actin, and a phenomenon that looks like treadmilling can be observed in live cells for individual microtubules ([Figure 16-10](#)).

The kinetic differences between the behavior of the T form and the D form have another important consequence for the behaviors of filaments. If the rate of subunit addition at one end is similar in magnitude to the rate of hydrolysis, there is a finite probability that this end will start out in a T form, but that hydrolysis will eventually "catch up" with the addition and transform the end to a D form. This transformation is sudden and random, with a certain probability per unit time. Thus, in a population of microtubules, at any instant some of the ends are in the T form, and some are in the D form, with the ratio depending on the hydrolysis rate and the free subunit concentration.

Suppose that the concentration of free subunits is intermediate between the critical concentration for a T-form end and the critical concentration for a D-

form end (that is, in the same range of concentrations where treadmilling is observed). Now, any end that happens to be in the T form will grow, whereas any end that happens to be in the D form will shrink. On a single filament, an end might grow for a certain length of time in a T form, but then suddenly change to the D form and begin to shrink rapidly, even while the free subunit concentration is held constant. At some later time, it might then regain a T-form and begin to grow again. This rapid interconversion between a growing and shrinking state, at a uniform free subunit concentration, is called dynamic instability (Figure 16-11). The change to rapid shrinkage is called a *catastrophe*, while the change to growth is called a *rescue*. In cells, dynamic instability is thought to predominate in microtubules, whereas treadmilling may predominate in actin filaments.

For microtubules, the structural difference between a T-form end and a D-form end is dramatic. Tubulin subunits with GTP bound to the β -monomer produce straight protofilaments that make strong and regular lateral contacts with one another. But the hydrolysis of GTP to GDP is associated with a subtle conformational change in the protein, which makes the protofilaments curved. On a rapidly growing microtubule, the GTP cap constrains the curvature of the protofilaments, and the ends appear straight. But when the terminal subunits have hydrolyzed their nucleotides, this constraint is released, and the curved protofilaments spring apart. This cooperative release of the energy of hydrolysis stored in the microtubule lattice results in the curled protofilaments peeling off rapidly, and rings and curved oligomers of GDP-containing tubulin are seen near the ends of depolymerizing microtubules (Figure 16-11C). [↑ TOP](#)

Treadmilling and Dynamic Instability Require Energy but Are Useful

Both dynamic instability and treadmilling allow a cell to maintain the same overall filament content, while individual subunits constantly recycle between the filaments and the cytosol. How dynamic are the microtubules and actin filaments inside a living cell? Typically, a microtubule, with major structural differences between its growing and shrinking ends, switches between growth and shrinkage a few times per minute. The ends of individual microtubules can therefore be seen in real time to exhibit such dynamic instability (Figure 16-12). For actin filaments, by contrast, the difference between the two types of ends is not so extreme, and the dynamic instability of an individual filament cannot be observed directly with the light microscope. With appropriate techniques based on fluorescence microscopy, however, one can show that actin filament turnover is typically rapid, with individual filaments persisting for only a few minutes.

At first glance, this dynamic behavior of filaments seems like a waste of energy. To maintain a constant concentration of actin filaments and microtubules, most of which are undergoing a process of either treadmilling or dynamic instability, the cell must hydrolyze large amounts of nucleoside

triphosphate. As we explained with our ant-trail analogy at the beginning of the chapter, the advantage to the cell seems to lie in the spatial and temporal flexibility that is inherent in a structural system with constant turnover. Individual subunits are small and can diffuse very rapidly; an actin or tubulin subunit can diffuse across the diameter of a typical eucaryotic cell in a second or two. As noted above, the rate-limiting step in the formation of a new filament is nucleation, so these rapidly diffusing subunits tend to assemble either on the ends of preexisting filaments or at special sites where the nucleation step is catalyzed by special proteins. The new filaments in either case are highly dynamic, and unless specifically stabilized, they have only a fleeting existence. By controlling where filaments are nucleated and selectively stabilized, a cell can control the location of its filament systems, and hence its structure. It seems that the cell is continually testing a wide variety of internal structures and only preserving those that are useful. When external conditions change, or when internal signals arise (as during the transitions in the cell cycle), the cell is poised to change its structure rapidly ([Figure 16-13](#)).

In certain specialized structures, particularly in various specialized cells in a multicellular organism, parts of the cytoskeleton become less dynamic. In a terminally differentiated cell such as a neuron, for example, it is desirable to maintain a consistent structure over time, and many of the actin filaments and microtubules are stabilized by association with other proteins. However, when new connections are made in the brain, as when the information you are reading here is transferred into long-term memory, even a cell as stable as a neuron can grow new processes to make new synapses. To do this, a neuron requires the inherently dynamic and exploratory activities of its cytoskeletal filaments. [↑ TOP](#)

Other Polymeric Proteins Also Use Nucleotide Hydrolysis to Couple a Conformational Change to Cell Movements

It is remarkable that actin and tubulin have both evolved nucleoside triphosphate hydrolysis for the same basic reason—to enable them to depolymerize readily after they have polymerized. Actin and tubulin are completely unrelated in amino acid sequence: actin is distantly related in structure to the glycolytic enzyme hexokinase, whereas tubulin is distantly related to a large family of GTPases that includes the heterotrimeric G proteins and monomeric GTPases such as Ras, structures that are discussed in [Chapter 3](#).

Several other types of protein polymers bind and hydrolyze nucleoside triphosphates. For example, *dynamain* assembles in helical coils around the base of membrane invaginations, helping to pinch off the invaginations to form vesicles (see [Figure 13-9](#)). Hydrolysis of GTP by dynamain generates a cooperative conformational change in the dynamain coil and provides the energy for the constriction. Bacteria and archaea have a tubulin homolog

called *FtsZ* that is essential for cell division. A band of FtsZ protein forms at the site of septation, where the new cell wall is to form. Constriction and disassembly of the FtsZ band then help to pinch the two daughter cells apart. *In vitro*, FtsZ forms protofilaments and rings reminiscent of tubulin, and it also binds and hydrolyzes GTP (Figure 16-14). The increase in ring curvature and disassembly of the FtsZ filaments is similar to the disassembly of curved GDP-tubulin protofilaments described earlier (see Figure 16-11), and it may occur by a similar mechanism.

These examples point to a second general way in which protein polymers can use the energy of nucleotide hydrolysis to affect cell structure and dynamics. In a linear protein polymer, a modest hydrolysis-linked conformational change by a few tenths of a nanometer in each subunit can be amplified by the thousands of subunits acting in parallel, so as to drive movements over tens or hundreds of nanometers. For dynamin and FtsZ, apparently, the effect of the GTP-dependent conformational changes is to bend lipid bilayers. [↑ TOP](#)

Tubulin and Actin Have Been Highly Conserved During Eucaryotic Evolution

Tubulin is found in all eucaryotic cells, and FtsZ has been found in all bacteria and archaea examined. Rod-shaped and spiral-shaped bacteria also contain an actin homolog, *MreB*, that forms filaments and regulates bacterial length. Thus, the principle of organizing cell structure by a self-association of nucleotide-binding proteins seems to be used in all cells.

Tubulin molecules themselves come in multiple isoforms. In mammals, there are at least six forms of α -tubulin and a similar number of forms of β -tubulin, each encoded by a different gene. The different forms of tubulin are very similar, and they generally copolymerize into mixed microtubules in the test tube, although they can have distinct locations in the cell and perform subtly different functions. As a particularly striking example, the microtubules in six specialized touch-sensitive neurons in the nematode *Caenorhabditis elegans* contain a specific form of β -tubulin, and mutations in the gene for this protein result in the loss of touch-sensitivity with no apparent defect in other cell functions.

Yeast and human tubulins are 75% identical in amino acid sequence. Most of the variation among different isoforms of tubulin is found in the amino acids near the C-terminus, which form a ridge on the surface of the microtubule. Thus, variations among isoforms are expected to affect primarily the association of accessory proteins with the surface of the microtubule, rather than microtubule polymerization *per se*.

Like tubulin, actin is found in all eucaryotic cells. Most organisms have multiple genes encoding actin; humans have six. Actin is extraordinarily well conserved among eucaryotes. The amino acid sequences of actins from

different species are usually about 90% identical. But, again like tubulin, small variations in actin amino acid sequence can create significant functional differences. In vertebrates, there are three subtly different isoforms of actin, termed α , β , and γ , that differ slightly in their amino acid sequences. The α -actin is expressed only in muscle cells, while β and γ are found together in almost all nonmuscle cells. Yeast actin and *Drosophila* muscle actin are 89% identical, yet the expression of yeast actin in *Drosophila* results in a fly that looks normal but is unable to fly.

What is the explanation for the unusually strict conservation of actin and tubulin in eucaryotic evolution? Most other cytoskeletal proteins, including intermediate filament proteins and the large families of accessory proteins that bind to actin or tubulin, are not particularly well conserved at the level of amino acid sequence. The likely explanation is that the structure of the entire surface of an actin filament or microtubule is constrained because so many other proteins must be able to interact with these two ubiquitous and abundant cell components. A mutation in actin that could result in a desirable change in its interaction with one other protein might cause undesirable changes in its interactions with a number of other proteins that bind at or near the same site. Genetic and biochemical studies in the yeast *Saccharomyces cerevisiae* have demonstrated that actin interacts directly with dozens of other proteins, and indirectly with even more (Figure 16-15). Over time, evolving organisms have found it more profitable to leave actin and tubulin alone, and alter their binding partners instead. [↑ TOP](#)

Intermediate Filament Structure Depends on The Lateral Bundling and Twisting of Coiled Coils

All eucaryotic cells contain actin and tubulin. But the third major type of cytoskeletal filament, the *intermediate filament*, is found in only some metazoans, including vertebrates, nematodes, and molluscs. Even in these organisms, intermediate filaments are not required in every cell type. The specialized glial cells (called oligodendrocytes) that make myelin in the vertebrate central nervous system, for example, do not contain intermediate filaments. Cytoplasmic intermediate filaments are closely related to their ancestors, the much more widely used *nuclear lamins*. The nuclear lamins are filamentous proteins that form a meshwork lining the inner membrane of the eucaryotic nuclear envelope, where they provide anchorage sites for chromosomes and nuclear pores (their dynamic behavior during cell division is discussed in [Chapter 12](#)). Several times during metazoan evolution, lamin genes have apparently duplicated, and the duplicates have evolved to produce rope-like, cytoplasmic intermediate filaments. These filaments have mechanical properties that are especially useful to soft-bodied animals such as nematodes and vertebrates that do not have an exoskeleton. Intermediate filaments are particularly prominent in the cytoplasm of cells that are subject to mechanical stress, and their major function seems to be to impart physical strength to cells and tissues.

The individual polypeptides of intermediate filaments are elongated molecules with an extended central α -helical domain that forms a parallel coiled coil with another monomer. A pair of parallel dimers then associates in an antiparallel fashion to form a staggered tetramer. This tetramer represents the soluble subunit that is analogous to the $\alpha\beta$ -tubulin dimer, or the actin monomer (Figure 16-16).

Since the tetrameric subunit is made up of two dimers pointing in opposite directions, its two ends are the same. The assembled intermediate filament therefore lacks the overall structural polarity that is critical for actin filaments and microtubules. The tetramers pack together laterally to form the filament, which includes eight parallel protofilaments made up of tetramers. Each individual intermediate filament therefore has a cross section of 32 individual α -helical coils. This large number of polypeptides all lined up together, with the strong lateral hydrophobic interactions typical of coiled-coil proteins, gives intermediate filaments a rope-like character. They can be easily bent but are extremely difficult to break (Figure 16-17).

Less is understood about the mechanism of assembly and disassembly of intermediate filaments than of actin filaments and microtubules, but they are clearly highly dynamic structures in most cell types. Under normal conditions, protein phosphorylation probably regulates their disassembly, in much the same way that phosphorylation regulates the disassembly of nuclear lamins in mitosis (see Figure 12-20). As evidence for a rapid turnover, labeled subunits microinjected into tissue culture cells rapidly add themselves onto the existing intermediate filaments within a few minutes, while an injection of peptides derived from a conserved helical region of the subunit induces the rapid disassembly of the intermediate filament network. Interestingly, the latter injection can induce the disassembly of the microtubule and actin filament networks in some cells that contain all three networks revealing that there is a fundamental mechanical integration among the different cytoskeletal systems in these cells. [↑ TOP](#)

Intermediate Filaments Impart Mechanical Stability to Animal Cells

Intermediate filaments come in a wide variety of types, with substantially more sequence variation in the subunit isoforms than occurs in the isoforms of actin or tubulin. A central α -helical domain has 40 or so heptad repeat motifs that form an extended coiled-coil (see Figure 3-11). This domain is similar in the different isoforms, but the N- and C-terminal globular domains can vary a great deal.

Different families of intermediate filaments are expressed in different cell types (Table 16-1). The most diverse intermediate filament family is that of the keratins: there are about 20 found in different types of human epithelial cells,

and about 10 more that are specific to hair and nails. A single epithelial cell may produce multiple types of keratins, and these copolymerize into a single network ([Figure 16-18](#)). Every keratin filament is made up of an equal mixture of type I (acidic) and type II (neutral/basic) keratin chains; these form heterodimers, two of which then join to form the fundamental tetrameric subunit (see [Figure 16-16](#)). Cross-linked keratin networks held together by disulfide bonds may survive even the death of their cells, forming tough coverings for animals, as in the outer layer of skin and in hair, nails, claws, and scales. The diversity in keratins is clinically useful in the diagnosis of epithelial cancers (carcinomas), as the particular set of keratins expressed gives an indication of the epithelial tissue in which the cancer originated and thus can help to guide the choice of treatment.

Mutations in keratin genes cause several human genetic diseases. For example, when defective keratins are expressed in the basal cell layer of the epidermis, they produce a disorder called *epidermolysis bullosa simplex*, in which the skin blisters in response to even very slight mechanical stress, which ruptures the basal cells ([Figure 16-19](#)). Other types of blistering diseases, including disorders of the mouth, esophageal lining, and the cornea of the eye, are caused by mutations in the different keratins whose expression is specific to those tissues. All of these maladies are typified by cell rupture as a consequence of mechanical trauma and a disorganization or clumping of the keratin filament cytoskeleton. Many of the specific mutations that cause these diseases alter the ends of the central rod domain, underlining the importance of this particular part of the protein for correct filament assembly.

A second family of intermediate filaments, called neurofilaments, is found in high concentrations along the axons of vertebrate neurons ([Figure 16-20](#)). Three types of neurofilament proteins (NF-L, NF-M, NF-H) coassemble *in vivo*, forming heteropolymers that contain NF-L plus one of the others. The NF-H and NF-M proteins have lengthy C-terminal tail domains that bind to neighboring filaments, generating aligned arrays with a uniform interfilament spacing. During axonal growth, new neurofilament subunits are incorporated all along the axon in a dynamic process that involves the addition of subunits along the filament length, as well as the addition of subunits at the filament ends. After an axon has grown and connected with its target cell, the diameter of the axon may increase as much as fivefold. The level of neurofilament gene expression seems to directly control axonal diameter, which in turn controls how fast electrical signals travel down the axon.

The neurodegenerative disease amyotrophic lateral sclerosis (ALS, or Lou Gehrig's Disease) is associated with an accumulation and abnormal assembly of neurofilaments in motor neuron cell bodies and in the axon, which may interfere with normal axonal transport. The degeneration of the axons leads to muscle weakness and atrophy, which is usually fatal. The overexpression of human NF-L or NF-H in mice results in mice that have an ALS-like disease.

The vimentin-like filaments are a third family of intermediate filaments. Desmin, a member of this family, is expressed in skeletal, cardiac, and smooth muscle. Mice lacking desmin show normal initial muscle development, but adults have a variety of muscle cell abnormalities, including misaligned muscle fibers.

Thus, intermediate filaments in general seem to serve as the ligaments of the cell, whereas microtubules and actin filaments seem to serve, respectively, as the bones and muscles of the cell. Just as we require our ligaments, bones, and muscles to work together, so all three cytoskeletal filament systems must normally function collectively to give a cell its strength, its shape, and its ability to move. [↑ TOP](#)

Filament Polymerization Can Be Altered by Drugs

Because the survival of eucaryotic cells depends on a balanced assembly and disassembly of the highly conserved cytoskeletal filaments formed from actin and tubulin, the two types of filaments are frequent targets for natural toxins. These toxins are produced in self-defense by plants, fungi, or sponges that do not wish to be eaten but cannot run away from predators, and they generally perturb the filament polymerization reaction. The toxin binds tightly to either the filament form or the free subunit form of a polymer, driving the assembly reaction in the direction that favors the form to which the toxin binds. For example, the drug *latrunculin*, extracted from the sea sponge *Latrunculia magnifica*, binds to and stabilizes actin monomers; it thereby causes a net depolymerization of actin filaments. In contrast, *phalloidin*, from the fungus *Amanita phalloides* (death cap), binds to and stabilizes actin filaments, causing a net increase in actin polymerization. (One remedy for *Amanita* mushroom poisoning is to eat a large quantity of raw meat: the high concentration of actin filaments in the muscle tissue binds the phalloidin and thereby reduces phalloidin's toxicity.) Either change in actin filaments is very toxic for cells. Similarly, *colchicine*, from the meadow saffron (or autumn crocus), binds to and stabilizes free tubulin, causing microtubule depolymerization. In contrast, *taxol*, extracted from the bark of a rare species of yew tree, binds to and stabilizes microtubules, causing a net increase in tubulin polymerization. These and some other natural products that are commonly used by cell biologists to manipulate the cytoskeleton are listed in [Table 16-2](#).

Drugs like these have a rapid and profound effect on the organization of the cytoskeleton in living cells ([Figure 16-21](#)). They provided early evidence that the cytoskeleton is a dynamic structure, maintained by a rapid and continual exchange of subunits between the soluble and filamentous forms and that this subunit flux is necessary for normal cytoskeletal function.

The drugs listed in [Table 16-2](#) have been useful to cell biologists trying to probe the roles of actin and microtubules in various cell processes. Some of them are also used in the treatment of cancer. Both microtubule-

depolymerizing drugs such as vinblastine and microtubule-polymerizing drugs such as taxol preferentially kill dividing cells, since both microtubule assembly and disassembly are crucial for correct function of the mitotic spindle (discussed in [Chapter 18](#)). These drugs efficiently kill certain types of tumor cells in a human patient, although not without toxicity to rapidly dividing normal cells, including those in the bone marrow, intestine, and hair follicles. Taxol in particular has been widely used to treat some specific cancers that are resistant to other chemotherapeutic agents.

The common laboratory reagent acrylamide, used as the precursor in making polyacrylamide gels for size separation of proteins and nucleic acids (see [Figure 8-14](#)), is also a cytoskeletal toxin. By an unknown mechanism, it causes the disassembly or rearrangement of intermediate filament networks. Acrylamide can be absorbed through the skin and acts as a potent neurotoxin by dismantling the neurofilament bundles in peripheral nerve axons. This is why it causes an unpleasant tingling sensation when spilled on bare skin and why it should always be handled cautiously. [↑ TOP](#)

Summary

The cytoplasm of eucaryotic cells is spatially organized by a network of protein filaments known as the cytoskeleton. This network contains three principal types of filaments: microtubules, actin filaments, and intermediate filaments. All three types of filaments form as helical assemblies of subunits that self-associate using a combination of end-to-end and side-to-side protein contacts. Differences in the structure of the subunits and the manner of their self-assembly give the filaments different mechanical properties. Intermediate filaments are rope-like and easy to bend but hard to break. Microtubules are strong, rigid hollow tubes. Actin filaments are the thinnest of the three and are hard to stretch but easy to break.

In living cells, all three types of cytoskeletal filaments undergo constant remodeling through the assembly and disassembly of their subunits. Microtubules and actin filaments add and lose subunits only at their ends, with one end (the plus end) growing faster than the other. Tubulin and actin (the subunits of microtubules and actin filaments, respectively) bind and hydrolyze nucleoside triphosphates (tubulin binds GTP and actin binds ATP). Nucleotide hydrolysis underlies the characteristic dynamic behavior of these two filaments. Actin filaments in cells seem to predominantly undergo treadmilling, where a filament assembles at one end while simultaneously disassembling at the other end. Microtubules in cells predominantly display dynamic instability, where a microtubule end undergoes alternating bouts of growth and shrinkage.

Whereas tubulin and actin have been strongly conserved in eucaryotic evolution, the family of intermediate filaments is very diverse. There are a variety of tissue-specific forms, including keratin filaments in epithelial cells,

neurofilaments in nerve cells, and desmin filaments in muscle cells. In all these cells, the primary job of intermediate filaments is to provide mechanical strength. [↑ TOP](#)

Figure 16-3. The thermal stability of cytoskeletal filaments with dynamic ends.

Formation of a cytoskeletal filament from more than one protofilament allows the ends to be dynamic, while the filaments themselves are resistant to thermal breakage. In this hypothetical example, the stable filament is formed from five protofilaments. The bonds holding the subunits together in the filaments are shown in red.

Figure 16-9. The treadmilling of an actin filament or microtubule, made possible by the nucleoside triphosphate hydrolysis that follows subunit addition. (A) Explanation for the different critical concentrations (C_c) at the plus and minus ends. Subunits with bound nucleoside triphosphate (T-form subunits) polymerize at both ends of a growing filament, and then undergo nucleotide hydrolysis in the filament lattice. As the filament grows, elongation is faster than hydrolysis at the plus end in this example, and the terminal subunits at this end are therefore always in the T form. However, hydrolysis is faster than elongation at the minus end, and so terminal subunits at this end are in the D form. (B) Treadmilling occurs at intermediate concentrations of free subunits. The critical concentration for polymerization on a filament end in the T form is lower than for a filament end in the D form. If the actual subunit concentration is somewhere between these two values, the plus end grows while the minus end shrinks, resulting in treadmilling.

Molecular Biology of the Cell → IV. Internal Organization of the Cell → 16. The Cytoskeleton → The Self-Assembly and Dynamic Structure of Cytoskeletal Filaments

Figure 16-10. Treadmilling behavior of a microtubule, as observed in a living cell. A cell was injected with tubulin that had been covalently linked to the fluorescent dye rhodamine, so that approximately 1 tubulin subunit in 20 was fluorescent. The fluorescence of individual microtubules was then observed with a sensitive electronic camera. The microtubule shown appears to

be sliding from *left* to *right*, but, in fact, the microtubule lattice remains stationary (as shown by the dark mark indicated by the *red* arrowhead), while the plus end (on the *right*) grows and the minus end (on the *left*) shrinks. At the same time, the plus end is displaying dynamic instability. (From C.M. Waterman-Storer and E.D. Salmon, *J. Cell Biol.* 139:417–434, 1997. © The Rockefeller University Press.)

Molecular Biology of the Cell → **IV. Internal Organization of the Cell** → **16. The Cytoskeleton** → **The Self-Assembly and Dynamic Structure of Cytoskeletal Filaments**

Figure 16-11. Dynamic instability due to the structural differences between a growing and a shrinking microtubule end. (A) If the free tubulin concentration in solution is between the critical values indicated in [Figure 16-9](#), a single microtubule end may undergo transitions between a growing state and a shrinking state. A growing microtubule has GTP-containing subunits at its end, forming a GTP cap. If nucleotide hydrolysis proceeds more rapidly than subunit addition, the cap is lost and the microtubule begins to shrink, an event called a "catastrophe." But GTP-containing subunits may still add to the shrinking end, and if enough add to form a new cap, then microtubule growth resumes, an event called "rescue." (B) Model for the structural consequences of GTP hydrolysis in the microtubule lattice. The addition of GTP-containing tubulin subunits to the end of a protofilament causes the end to grow in a linear conformation that can readily pack into the cylindrical wall of the microtubule. Hydrolysis of GTP after assembly changes the conformation of the subunits and tends to force the protofilament into a curved shape that is less able to pack into the microtubule wall. (C) In an intact microtubule, protofilaments made from GDP-containing subunits are forced into a linear conformation by the many lateral bonds within the microtubule wall, given a stable cap of GTP-containing subunits. Loss of the GTP cap, however, allows the GDP-containing protofilaments to relax into their more curved conformation. This leads to a

progressive disruption of the microtubule. Above the drawings of a growing and a shrinking microtubule, electron micrographs show actual microtubules in each of these two states, as observed in preparations in vitreous ice. Note particularly the curling, disintegrating GDP-containing protofilaments at the end of the shrinking microtubule. (C, courtesy of E.M. Mandelkow, E. Mandelkow and R.A. Milligan, *J. Figure 16-17. Mechanical properties of actin, tubulin, and intermediate filament polymers. Networks composed of microtubules, actin filaments, or a type of intermediate filament called vimentin, all at equal concentration, were exposed to a shear force in a viscometer, and the resulting degree of stretch was measured. The results show that microtubule networks are easily deformed but that they rupture (indicated by *red starburst*) and begin to flow without limit when stretched beyond 150% of their original length. Actin filament networks are much more rigid, but they also rupture easily. Intermediate filament networks, by contrast, are not only easily deformed, but they withstand large stresses and strains without rupture; they are thereby well suited to maintain cell integrity. Figure 16-19. Blistering of the skin caused by a mutant keratin gene. A mutant gene encoding a truncated keratin protein (lacking both the N- and C-terminal domains) was expressed in a transgenic mouse. The defective protein assembles with the normal keratins and thereby disrupts the keratin filament network in the basal cells of the skin. Light micrographs of cross sections of normal (A) and mutant (B) skin show that the blistering results from the rupturing of cells in the basal layer of the mutant epidermis (small *red* arrows). (C) A sketch of three cells in the basal layer of the mutant epidermis, as observed by electron microscopy. As indicated by the *red* arrow, the cells rupture between the nucleus and the hemidesmosomes (discussed in [Chapter 19](#)), which connect the keratin filaments to the underlying basal lamina. 16-1. The Three Major Types of Protein that Form the Cytoskeleton

ACTIN FILAMENTS

Actin filaments (also known as *microfilaments*) are two-stranded helical polymers of the protein actin. They appear as flexible structures, with a diameter of 5–9 nm, and they are organized into a variety of linear bundles, two-dimensional networks, and three-dimensional gels. Although actin filaments are dispersed throughout the cell, they are most highly concentrated in the *cortex*, just beneath the plasma membrane.

MICROTUBULES

Search

Go

This book

All books

PubMed

Microtubules are long, hollow cylinders made of the protein tubulin. With an outer diameter of 25 nm, they are much more rigid than actin filaments. Microtubules are long and straight and typically have one end attached to a single microtubule-organizing center (MTOC) called a *centrosome*, as shown here.

Micrographs courtesy of Richard Wade (i); D.T. Woodrow and R.W. Linck (ii); David Shima (iii); A. Desai (iv).

INTERMEDIATE FILAMENTS

Intermediate filaments are ropelike fibers with a diameter of around 10 nm; they are made of intermediate filament proteins, which constitute a large and heterogeneous family. One type of intermediate filament forms a meshwork called the nuclear lamina just beneath the inner nuclear membrane. Other types extend across the cytoplasm, giving cells mechanical strength. In an epithelial tissue, they span the cytoplasm from one cell-cell junction to another, thereby strengthening the entire epithelium.

16-2. The Polymerization of Actin and Tubulin

ON RATES AND OFF RATES

A linear polymer of protein molecules, such as an actin filament or a microtubule, assembles (polymerizes) and disassembles (depolymerizes) by the addition and removal of subunits at the ends of the polymer. The rate of addition of these subunits (called monomers) is given by the rate constant k_{on} , which has units of $M^{-1} sec^{-1}$. The rate of loss is given by k_{off} (units of sec^{-1}).

NUCLEATION

A helical polymer is stabilized by multiple contacts between adjacent subunits. In the case of actin, two actin molecules bind relatively weakly to each other, but addition of a third actin monomer to form a trimer makes the entire group more stable.

Further monomer addition can take place onto this trimer, which therefore acts as a **nucleus** for polymerization. For tubulin, the nucleus is larger and has a more complicated structure (possibly a ring of 13 or more tubulin molecules)—but the principle is the same.

The assembly of a nucleus is relatively slow, which explains the lag phase seen during polymerization. The lag phase can be reduced or abolished entirely if premade nuclei, such as fragments of already polymerized microtubules or actin filaments, are added.

THE CRITICAL CONCENTRATION

The number of monomers that add to the polymer (actin filament or microtubule) per second will be proportional to the

TIME COURSE OF POLYMERIZATION

The assembly of a protein into a long helical polymer such as a cytoskeletal filament or a bacterial flagellum typically shows the following time course:

EQUILIBRIUM

Search

This book

All books

PubMed

concentration of the free subunit ($k_{on}C$), but the subunits will leave the polymer end at a constant rate (k_{off}) that does not depend on C . As the polymer grows, subunits are used up, and C is observed to drop until it reaches a constant value, called the **critical concentration** (C_c). At this concentration the rate of subunit addition equals the rate of subunit loss.

At this equilibrium,

$$k_{on} C = k_{off}$$

so that

$$C_c = \frac{k_{off}}{k_{on}} = \frac{1}{K}$$

(where K is the equilibrium constant for subunit addition; see Figure 3-44).

The **lag phase** corresponds to time taken for nucleation.

The **growth phase** occurs as monomers add to the exposed ends of the growing filament, causing filament elongation.

The **equilibrium phase**, or **steady state**, is reached when the growth of the polymer due to monomer addition is precisely balanced by the shrinkage of the polymer due to disassembly back to monomers.

PLUS AND MINUS ENDS

The two ends of an actin filament or microtubule polymerize at different rates. The fast-growing end is called the **plus end**, whereas the slow-growing end is called the **minus end**. The difference in the rates of growth at the two ends is made possible by changes in the conformation of each subunit as it enters the polymer.

This conformational change affects the rates at which subunits add to the two ends.

Even though k_{on} and k_{off} will have different values for the plus and minus ends of the polymer, their ratio k_{off}/k_{on} —and hence C_c —must be the same at both ends for a simple polymerization reaction (no ATP or GTP hydrolysis). This is because exactly the same subunit interactions are broken when a subunit is lost at either end, and the final state of

the subunit after dissociation is identical. Therefore, the ΔG for subunit loss, which determines the equilibrium constant for its association with the end, is identical at both ends: if the plus end grows four times faster than the minus end, it must also shrink four times faster. Thus, for $C > C_c$, both ends grow; for $C < C_c$, both ends shrink.

The nucleoside triphosphate hydrolysis that accompanies actin and tubulin polymerization removes this constraint.

NUCLEOTIDE HYDROLYSIS

Each actin molecule carries a tightly bound ATP molecule that is hydrolyzed to a tightly bound ADP molecule soon after its assembly into polymer. Similarly, each tubulin molecule carries a tightly bound GTP that is converted to a tightly bound GDP molecule soon after the molecule assembles into the polymer.

ATP CAPS AND GTP CAPS

The rate of addition of subunits to a growing actin filament or microtubule can be faster than the rate at which their

Each molecule soon enters the molecule and assembles into the polymer:

Hydrolysis of the bound nucleotide reduces the binding affinity of the subunit for neighboring subunits and makes it more likely to dissociate from each end of the filament (see Figure 16-11 for a possible mechanism). It is usually the T form that adds to the filament and the D form that leaves.

Considering events at the plus end only:

As before, the polymer will grow until $C = C_c$. For illustrative purposes, we can ignore k^D_{on} and k^T_{off} since they are usually very small, so that polymer growth ceases when

$$k^T_{\text{on}} C = k^D_{\text{off}} \quad \text{or} \quad C_c = \frac{k^D_{\text{off}}}{k^T_{\text{on}}}$$

This is a steady state and not a true equilibrium, because the ATP or GTP that is hydrolyzed must be replenished by a nucleotide exchange reaction of the free subunit ($\text{D} \rightarrow \text{T}$).

bound nucleotide is hydrolyzed. Under such conditions, the end has a "cap" of subunits containing the nucleoside triphosphate—an ATP cap on an actin filament or a GTP cap on a microtubule.

DYNAMIC INSTABILITY and **TREADMILLING** are two behaviors observed in cytoskeletal polymers. Both are associated with nucleoside triphosphate hydrolysis. Dynamic instability is believed to predominate in microtubules, whereas treadmilling may predominate in actin filaments.

TREADMILLING

One consequence of the nucleotide hydrolysis that accompanies polymer formation is to change the critical concentration at the two ends of the polymer. Since k^D_{off} and k^T_{on} refer to different reactions, their ratio $k^D_{\text{off}}/k^T_{\text{on}}$ need not be the same at both ends of the polymer, so that:

$$C_c (\text{minus end}) > C_c (\text{plus end})$$

Thus, if both ends of a polymer are exposed, polymerization proceeds until the concentration of free monomer reaches a value that is above C_c for the plus end but below C_c for the minus end. At this steady state, subunits undergo a net assembly at the plus end and a net disassembly at the minus end at an identical rate. The polymer maintains a constant length, even though there is a net flux of subunits through the polymer, known as **treadmilling**.

How Cells Regulate Their Cytoskeletal Filaments

Microtubules, actin filaments, and intermediate filaments are much more dynamic in cells than they are in the test tube. The cell regulates the length and stability of its cytoskeletal filaments, as well as their number and the geometry. It does so largely by regulating their attachments to one another and to other components of the cell, so that the filaments can form a wide variety of higher-order structures. Some filament properties are regulated by direct covalent modification of the filament subunits, but most of the regulation is performed by accessory proteins that bind to either the filaments or their free subunits.

This section focuses on how these accessory proteins modify the dynamics and structure of cytoskeletal filaments. We begin with a discussion of how microtubules and actin filaments are nucleated in cells, as this plays a major part in determining the overall organization of the cell's interior.

Microtubules Are Nucleated by a Protein Complex Containing γ -tubulin

While α - and β -tubulins are the regular building blocks of microtubules, another type of tubulin, called γ -tubulin, has a more specialized role. Present in much smaller amounts than α - and β -tubulin, this protein is involved in the nucleation of microtubule growth in organisms ranging from yeasts to humans. Microtubules are generally nucleated from a specific intracellular location known as a **microtubule-organizing center (MTOC)**. Antibodies against γ -tubulin stain the MTOC in virtually all species and cell types thus far examined.

Microtubules are nucleated at their minus end, with the plus end growing outward from each MTOC to create various types of microtubule arrays. A **γ -tubulin ring complex (γ -TuRC)** has been isolated from both insect and vertebrate cells and is an impressively efficient nucleator of microtubule growth in a test tube. Two proteins, conserved from yeasts to humans, bind directly to the γ -tubulin, along with several other proteins that help create the ring that can be seen at the minus ends of the microtubules nucleated by γ -

TuRC. This ring of γ -tubulin molecules is therefore thought to serve as a template that nucleates a microtubule with 13 protofilaments ([Figure 16-22](#)). [↑ TOP](#)

Microtubules Emanate from the Centrosome in Animal Cells

In most animal cells, there is a single, well-defined MTOC called the centrosome, located near the nucleus. From this focal point, the cytoplasmic microtubules emanate in a star-like, "astral" conformation. Microtubules are nucleated at the centrosome at their minus ends, so the plus ends point outward and grow toward the cell periphery. A centrosome is composed of a fibrous *centrosome matrix* that contains more than fifty copies of γ -TuRC. Most of the proteins that form this matrix, remain to be discovered, and it is not yet known how they recruit and activate the γ -TuRC.

Embedded in the centrosome is a pair of cylindrical structures arranged at right angles to each other in an L-shaped configuration ([Figure 16-23](#)). These are the centrioles, which become the basal bodies of cilia and flagella in motile cells (described later). The centrioles organize the centrosome matrix (also called the pericentriolar material), ensuring its duplication during each cell cycle as the centrioles themselves duplicate. As described in [Chapter 18](#), the centrosome duplicates and splits into two equal parts during interphase, each half containing a duplicated centriole pair (see [Figure 18-6](#)). These two daughter centrosomes move to opposite sides of the nucleus when mitosis begins, and they form the two poles of the mitotic spindle (see [Figure 18-7](#)). A centriole consists of a short cylinder of modified microtubules, plus a large number of accessory proteins ([Figure 16-24](#)). The molecular basis for its duplication is not known.

In fungi and diatoms, microtubules are nucleated at an MTOC that is embedded in the nuclear envelope as a small plaque called the *spindle pole body*. Higher-plant cells seem to nucleate microtubules at sites distributed all around the nuclear envelope. Neither fungi nor most plant cells contain centrioles. Despite these differences, all these cells contain γ -tubulin and seem to use it to nucleate their microtubules.

In animal cells, the astral configuration of microtubules is very robust, with dynamic plus ends pointing outward toward the cell periphery and stable minus ends collected near the nucleus. The system of microtubules radiating from the centrosome acts as a device to survey the outlying regions of the cell and position the centrosome at its center, and it does this even in artificial enclosures ([Figure 16-25](#)). Even in an isolated cell fragment lacking the centrosome, dynamic microtubules interacting with membraneous organelles and motor proteins arrange themselves into a star-shaped array with the microtubule minus ends clustered at the center ([Figure 16-26](#)). This ability of the microtubule cytoskeleton to find the center of the cell establishes a general

coordinate system, which is then used to position many organelles within the cell. [↑ TOP](#)

Actin Filaments Are Often Nucleated at the Plasma Membrane

In contrast to microtubule nucleation, which occurs primarily deep within the cytoplasm near the nucleus, actin filament nucleation most frequently occurs at the plasma membrane ([Figure 16-27](#)). Consequently, the highest density of actin filaments in most cells is at the cell periphery. These actin filaments in the layer underlying the plasma membrane, called the cell cortex, determine the shape and movement of the cell surface. For example, depending on their attachments to one another and to the plasma membrane, actin structures can form many strikingly different types of cell surface projections. These include spiky bundles such as *microvilli* or *filopodia*, flat protrusive veils called *lamellipodia* that help move cells over solid substrates, and the phagocytic cups in macrophages.

The nucleation of actin filaments at the plasma membrane is frequently regulated by external signals, allowing the cell to change its shape and stiffness rapidly in response to changes in its external environment. This nucleation is catalyzed by a complex of proteins that includes two *actin-related proteins*, or *ARPs*, each of which is about 45% identical to actin. Analogous to the function of the γ -TuRC, the ARP complex (also known as the *Arp 2/3 complex*) nucleates actin filament growth from the minus end, allowing rapid elongation at the plus end. However, the complex can also attach to the side of another actin filament while remaining bound to the minus end of the filament that it has nucleated, thereby building individual filaments into a treelike web ([Figure 16-28](#)). The ARP complex is localized in regions of rapid actin filament growth such as lamellipodia, and its nucleating activity is regulated by intracellular signaling molecules and components at the cytosolic face of the plasma membrane.

Both γ -tubulin and ARPs are evolutionarily ancient, and they are conserved among a wide variety of eucaryotic species. Their genes seem to have arisen by early duplication of the gene for the microtubule or actin filament subunit, respectively, followed by divergence and specialization of the gene copies so that they encode proteins with a special nucleating function. That a similar strategy has evolved for two separate cytoskeletal systems underlines the central importance of regulated filament nucleation as a general organizing principle in cells. [↑ TOP](#)

Filament Elongation Is Modified by Proteins That Bind to the Free Subunits

the addition of soluble subunits. In most nonmuscle vertebrate cells, approximately 50% of the actin is in filaments and 50% is soluble. The soluble monomer concentration is typically 50–200 μM (2–8 mg/ml), which is surprisingly high, given the low critical concentration observed for pure actin in a test tube (less than 1 μM). Why does the soluble actin not polymerize into filaments? The reason is that the abundant subunit pool contains special proteins that bind to the actin monomers, thereby making polymerization much less favorable (the action is similar to that of latrunculin). A small protein called *thymosin* is the most abundant of these proteins. Actin monomers bound to thymosin are in a locked state, where they cannot associate with either the plus or minus ends of actin filament and cannot hydrolyze or exchange their bound nucleotide.

How do cells recruit actin monomers from this sequestered pool and use them for polymerization? One might imagine that the thymosin itself could be regulated by signal transduction pathways, but this has not been found to be the case. Instead, recruitment depends on another monomer-binding protein, *profilin*. Profilin binds to the face of the actin monomer opposite the ATP-binding cleft, blocking the side of the monomer that would normally associate with the filament minus end (Figure 16-29). However, the profilin-actin complex can readily add onto a free plus end. As soon as this addition occurs, a conformational change is induced in the actin that reduces its affinity for profilin, so the profilin falls off, leaving the actin filament one subunit longer. Profilin competes with thymosin in binding to individual actin monomers, and a local activation of profilin molecules moves actin subunits from the sequestered thymosin-bound pool onto filament plus ends (Figure 16-30).

Several types of intracellular mechanisms regulate the activity of profilin, including profilin phosphorylation and profilin binding to inositol phospholipids. These mechanisms can define the sites where profilin acts. Profilin's ability to move sequestered actin subunits onto the growing ends of filaments is critical for filament assembly at the plasma membrane, for example. Profilin is localized at the cytosolic face of the plasma membrane because it binds to acidic membrane phospholipids there. At this location, extracellular signals can produce explosive local actin polymerization and the extension of actin-rich motile structures such as filopodia and lamellipodia (see below). Besides binding to actin and phospholipids, profilin also binds to various other intracellular proteins that have domains rich in proline; these proteins may also help to localize profilin to sites where rapid actin assembly may be required.

Like actin monomers, unpolymerized tubulin subunits are sequestered in the cell to maintain the subunit pool at a level substantially higher than the critical concentration. One molecule of the small protein *stathmin* binds to two tubulin heterodimers and prevents their addition onto the ends of microtubules. Stathmin thus decreases the effective concentration of tubulin subunits that are available for polymerization (the action is analogous to that of colchicine). High levels of active stathmin in a cell decrease the elongation rate of

microtubules, since the elongation rate is just the product of the concentration of available tubulin subunits and the rate constant k_{on} . The slower elongation rate also has a second remarkable effect. Since the transition from the growing state to the shrinking state for a microtubule undergoing dynamic instability depends on the race between GTP hydrolysis and filament elongation, slowing the elongation rate by sequestering tubulin subunits can increase the frequency of microtubule shrinkage. Thus, a protein that inhibits tubulin polymerization can have the secondary effect of dramatically increasing the dynamic turnover of microtubules in living cells ([Figure 16-31](#)).

Stathmin's binding to tubulin is inhibited by the phosphorylation of stathmin, and signals that result in stathmin phosphorylation can increase the rate of microtubule elongation and suppress dynamic instability. [↑ TOP](#)

Proteins That Bind Along the Sides of Filaments Can Either Stabilize or Destabilize Them

Once a cytoskeletal filament is formed by nucleation and elongated from the subunit pool, its stability and mechanical properties are often altered by a set of proteins that bind along the sides of the polymer. Different filament-associated proteins use their binding energy to either lower or raise the free energy of the polymer state, and they thereby either stabilize or destabilize the polymer, respectively.

Proteins that bind along the sides of microtubules are collectively called microtubule-associated proteins, or **MAPs**. Like the drug taxol, MAPs can stabilize microtubules against disassembly. A subset of MAPs can also mediate the interaction of microtubules with other cellular components. This subset is prominent in neurons, where stabilized microtubule bundles form the core of the axons and dendrites that extend from the cell body ([Figure 16-32](#)). These MAPs have at least one domain that binds to the microtubule surface and another that projects outward. The length of the projecting domain can determine how closely MAP-coated microtubules pack together, as demonstrated in cells engineered to overproduce different MAPs. Cells overexpressing *MAP2*, which has a long projecting domain, form bundles of stable microtubules that are kept widely spaced, while cells overexpressing *tau*, a MAP with a much shorter projecting domain, form bundles of more closely packed microtubules ([Figure 16-33](#)).

The microtubule-binding domain of several MAPs, including tau and MAP2, includes multiple copies of a tubulin-binding motif. When such MAPs are added to a solution of pure unpolymerized tubulin, they greatly accelerate nucleation, presumably because they stabilize the small tubulin oligomers that form early in polymerization. MAPs are the targets of several protein kinases, and the resulting phosphorylation of a MAP can have a primary role in controlling both its activity and localization inside cells.

Whereas MAP2 and tau are confined to selected cell types in vertebrates, there are other MAPs that seem to have a central role in microtubule dynamics in nearly all eucaryotic cells. In particular, a ubiquitous protein called *XMAP215* has close homologs in organisms that range from yeast to humans (*XMAP* stands for *Xenopus* microtubule-associated protein, and the number refers to its molecular weight). This protein binds along the sides of microtubules, but, as discussed later, it also has a special ability to stabilize free microtubule ends and inhibit their switch from a growing to a shrinking state. The phosphorylation of *XMAP215* during mitosis inhibits this activity, making a substantial contribution to the tenfold increase in the dynamic instability of microtubules observed during mitosis (see [Figure 18-12](#)).

Actin filaments are likewise strongly affected by the binding of accessory proteins along their sides. Selected actin filaments in most cells are stabilized by the binding of *tropomyosin*, an elongated protein that binds simultaneously to seven adjacent actin subunits in one protofilament. The binding of tropomyosin along an actin filament can prevent the filament from interacting with other proteins; for this reason, the regulation of tropomyosin binding is an important step in muscle contraction, as we discuss later (see [Figure 16-74](#)).

Another important actin-filament binding protein present in all eucaryotic cells is *cofilin*, which destabilizes actin filaments. Also called *actin depolymerizing factor*, cofilin is unusual in that it binds to actin in both the filament and free subunit forms. Cofilin binds along the length of the actin filament, forcing the filament to twist a little more tightly ([Figure 16-34](#)). This mechanical stress weakens the contacts between actin subunits in the filament, making the filament brittle and more easily severed. In addition, it makes it easier for an ADP-actin subunit to dissociate from the minus end of the filament. Because the rate of actin filament treadmilling is normally limited by the slow dissociation rate at the minus end, cofilin binding causes a large increase in the rate of actin filament treadmilling. As a result, most of the actin filaments inside cells are much shorter-lived than are filaments formed from pure actin in a test tube.

Cofilin binds preferentially to ADP-containing actin filaments rather than to ATP-containing filaments. Since ATP hydrolysis is usually slower than filament assembly, the newest actin filaments in the cell still contain mostly ATP and are resistant to depolymerization by cofilin. Cofilin therefore efficiently dismantles the older filaments in the cell, ensuring that all actin filaments turn over rapidly. [↑ TOP](#)

Proteins That Interact with Filament Ends Can Dramatically Change Filament Dynamics

As we have just seen, proteins that bind along the side of a filament can change the filament's dynamic behavior. For maximum effect, however, these proteins often need to coat the filament completely, and this means they have

to be present at fairly high stoichiometries (for example, about one tropomyosin for every seven actin subunits, one tau for every four tubulin subunits, or one cofilin for every actin subunit). In contrast, proteins that bind preferentially to the ends of filaments can have dramatic effects on filament dynamics even when they are present at very low levels. Since subunit addition and loss occur primarily at filament ends, one molecule of such a protein per actin filament (typically one per about 200–500 actin monomers) can be enough to transform the architecture of an actin filament network.

As previously discussed, an actin filament that ceases elongation and is not specifically stabilized by the cell can depolymerize rapidly: it can lose subunits from either its plus or its minus end, once the actin molecules at that end have hydrolyzed their ATP to convert to the D form. The most rapid changes, however, occur at the plus end. An actin filament can be stabilized at its plus end by the binding of a plus end *capping protein*, which greatly slows the rates of both filament growth and filament depolymerization by making the plus end inactive ([Figure 16-35](#)). Indeed, most of the actin filaments in a cell are capped at their plus end by proteins such as *CapZ* (named for its location in the muscle Z band, see below; it is also called Capping Protein). At the minus end, an actin filament may be capped by remaining bound to the ARP complex that was responsible for its nucleation, although it is possible that many of the actin filament minus ends in typical cells are released from the ARP complex and are uncapped.

A local regulation of the level of capping helps cells to assemble and dismantle specific parts of their actin cytoskeleton. The association of capping proteins with actin filament ends is regulated by various localized intracellular signals. The regulation of plus end capping proteins by the inositol phospholipid PIP₂ is especially important: an increase in PIP₂ in the cytosolic leaflet of the plasma membrane caused by activation of an appropriate cell surface receptor (discussed in [Chapter 15](#)) uncaps plus ends. The uncapping makes the plus ends available for elongation, thereby promoting actin filament polymerization at the cell surface.

In muscle cells, where actin filaments are exceptionally long-lived, the filaments are known to be specially capped at both ends—by *CapZ* at the plus end and by *tropomodulin* at the minus end. Tropomodulin binds only to the minus end of actin filaments that have been coated by tropomyosin and have thereby already been somewhat stabilized.

The end of a microtubule, with thirteen protofilaments in a hollow ring (see [Figure 16-6](#)), is a much larger and more complex structure than the end of an actin filament, with many more possibilities for accessory protein action. We have already discussed an important microtubule capper: the γ -tubulin ring complex (γ -TuRC), which both nucleates the growth of microtubules at an organizing center and caps their minus ends. Another true capping protein for microtubules is the special protein complex found at the ends of the

microtubules in cilia (discussed later), where microtubules are both stable and uniform in length.

Some proteins that act at the ends of microtubules have crucial roles beyond those expected for a simple capping protein. In particular, they can have dramatic effects on the dynamic instability of microtubules (see [Figure 16-11](#)). They can influence the rate at which a microtubule switches from a growing to a shrinking state (the frequency of catastrophes) or from a shrinking to a growing state (the frequency of rescues). For example, a family of kinesin-related proteins known as *catastrophins* induce catastrophes. They bind specifically to ends and seem to pry protofilaments apart, lowering the normal activation energy barrier that prevents a microtubule from springing apart into the curved protofilament characteristic of the shrinking state (see [Figure 16-11C](#)). Opposing their actions are MAPs that bind preferentially to ends to favor continued microtubule growth ([Figure 16-36A](#)). Both groups of proteins are regulated, and a greatly altered balance between their activities causes the major increase in microtubule turnover rates observed during mitosis (see [Figure 18-12](#)).

Proteins that bind to the ends of microtubules also serve to control microtubule positioning. In addition to γ -TuRC at the minus ends, there are several groups of plus-end-binding proteins that help localize the growing microtubule end to specific target proteins in the cell cortex. An end-binding protein present in both yeasts and humans, for example, is essential for yeast mitotic spindle positioning, directing the growing plus ends of yeast spindle microtubules to a specific docking region in the yeast bud and then helping to anchor them there ([Figure 16-36B](#)). [↑ TOP](#)

Filaments Are Organized into Higher-order Structures in Cells

So far, we have described how cells use accessory proteins to regulate the location and dynamic behavior of cytoskeletal filaments. These proteins can nucleate filament assembly, bind to the ends or sides of the filaments, or bind to the free subunits of filaments. But in order for the cytoskeletal filaments to form a useful intracellular scaffold that gives the cell mechanical integrity and determines its shape, the individual filaments must be organized and tied together into larger-scale structures. The centrosome is one example of such a cytoskeletal organizer; in addition to nucleating the growth of microtubules, it holds them together in a defined geometry, with all of the minus ends buried in the centrosome and the plus ends pointing outward. In this way, the centrosome creates the astral array of microtubules that is able to find the center of each cell (see [Figure 16-25](#)).

Another mechanism that is used to organize filaments into large structures is filament cross-linking. Any tendency of filaments to stick to one another

causes them to align in parallel arrays so as to maximize interfilament contacts. As described earlier, some MAPs can bundle microtubules together: they have two domains—one that binds along the microtubule side (and thereby stabilizes the filament) and another that projects outward to contact other MAP-coated microtubules. In the actin cytoskeleton, the stabilizing and cross-linking functions are separated. Tropomyosin binds along the sides of actin filaments, but it does not have an outward projecting domain. Filament cross-linking is instead mediated by a second group of actin-binding proteins that have only this function. Intermediate filaments are different yet again; they are organized both by a lateral self-association of the filaments themselves and by the cross-linking activity of accessory proteins. [↑ TOP](#)

Intermediate Filaments Are Cross-linked and Bundled Into Strong Arrays

Each individual intermediate filament forms as a long bundle of tetrameric subunits (see [Figure 16-16](#)). Many intermediate filaments further bundle themselves by self-association; for example, the neurofilament proteins NF-M and NF-H contain a C-terminal domain that extends outward from the surface of the assembled intermediate filament and binds to a neighboring filament. Thus groups of neurofilaments form robust parallel arrays that are held together by multiple lateral contacts, giving strength and stability to the long cell processes of neurons (see [Figure 16-20](#)).

Other types of intermediate filament bundles are held together by accessory proteins, such as *filaggrin*, which bundles keratin filaments in differentiating cells of the epidermis to give the outermost layers of the skin their special toughness. *Plectin*, which makes bundles of vimentin, is a particularly interesting cross-linking protein. Besides bundling intermediate filaments, it also links the intermediate filaments to microtubules, actin filament bundles, and filaments of the motor protein myosin II (discussed below), as well as helping to attach intermediate filament bundles to adhesive structures at the plasma membrane ([Figure 16-37](#)). Mutations in the gene for plectin cause a devastating human disease that combines epidermolysis bullosa (caused by disruption of skin keratin filaments), muscular dystrophy (caused by disruption of desmin filaments), and neurodegeneration (caused by disruption of neurofilaments). Mice lacking a functional plectin gene die within a few days of birth, with blistered skin and abnormal skeletal and heart muscles. Thus, although plectin may not be necessary for the initial formation and assembly of intermediate filaments, its cross-linking action is required to provide cells with the strength they need to withstand the mechanical stresses inherent to vertebrate life. [↑ TOP](#)

Cross-linking Proteins with Distinct Properties Organize Different Assemblies of Actin Filaments

Actin filaments in animal cells are organized into two types of arrays: bundles and weblike (gel-like) networks ([Figure 16-38](#)). Actin filament cross-linking proteins are accordingly divided into two classes, *bundling proteins* and *gel-forming proteins*. Bundling proteins cross-link actin filaments into a parallel array, while gel-forming proteins hold two actin filaments together at a large angle to each other, thereby creating a looser meshwork. Both types of cross-linking protein generally have two similar actin-filament-binding sites, which can either be part of a single polypeptide chain or contributed by each of two polypeptide chains held together in a dimer. The spacing and arrangement of these two filament-binding domains determines the type of actin structure that a given cross-linking protein forms ([Figure 16-39](#)).

Fimbrin and α -*actinin* are widely distributed actin-bundling proteins. Fimbrin is a small crosslinker, with two actin-binding domains close together in a single polypeptide chain. It is enriched in the parallel actin filament bundles in filopodia at the leading edge of cells, and it is presumably responsible for the tight association of these actin filaments ([Figure 16-40](#)). α -actinin contains two actin-binding domains that are further apart (see [Figure 16-40A](#) and [B](#)); it is concentrated in stress fibers, where it is responsible for the relatively loose cross-linking of actin filaments in these contractile bundles. It also helps form the structure that holds stress fiber ends in *focal contacts* at the plasma membrane (see below).

Each type of bundling protein determines which other molecules can interact with an actin filament. Myosin II (discussed later) is the protein in stress fibers and other contractile arrays that is responsible for their ability to contract. The very close packing of actin filaments caused by fimbrin apparently excludes myosin, and thus filopodia are not contractile; on the other hand, the looser packing caused by α -actinin allows myosin molecules to enter, making stress fibers contractile (see [Figure 16-40A](#)). Because of the very different spacing between the actin filaments, bundling by fimbrin automatically discourages bundling by α -actinin, and vice-versa, so that the two types of bundling protein are themselves mutually exclusive.

Villin is another bundling protein that, like fimbrin, has two actin-filament-binding sites very close together in a single polypeptide chain. Villin (together with fimbrin) helps cross-link the 20 to 30 tightly bundled actin filaments found in microvilli, the finger-like extensions of the plasma membrane on the surface of many epithelial cells ([Figure 16-41](#)). A single absorptive epithelial cell in the human small intestine, for example, has several thousand microvilli on its apical surface. Each is about 0.08 μm wide and 1 μm long, making the cell's absorptive surface area about 20 times greater than it would be without microvilli. When villin is introduced into cultured fibroblasts, which do not normally contain villin and have only a few small microvilli, the existing microvilli become greatly elongated and stabilized, and new ones are induced. The actin filament core of the microvillus is attached to the plasma membrane along its sides by lateral sidearms made of *myosin I* (discussed later), which

has a binding site for filamentous actin on one end and a domain that binds lipids on the other end. These two types of cross-linkers, one binding actin filaments to each other and the other binding these filaments to the membrane, seem to be sufficient to form microvilli on cells.

The various bundling proteins that we have discussed so far have straight, stiff connections between their two actin-filament-binding domains, and they tend to align filaments in parallel bundles. In contrast, those actin cross-linking proteins that have either a flexible or a stiff, bent connection between their two binding domains form actin filament webs or gels, rather than actin bundles.

A well-studied web-forming protein is *spectrin*, which was first identified in red blood cells. Spectrin is a long, flexible protein made out of four elongated polypeptide chains (two α subunits and two β subunits), arranged so that the two actin-filament-binding sites are about 200 nm apart (compared with 14 nm for fimbrin and about 30 nm for α -actinin, see [Figure 16-39](#)). In the red blood cell, spectrin is concentrated just beneath the plasma membrane, where it forms a two-dimensional web held together by short actin filaments; spectrin links this web to the plasma membrane because it has separate binding sites for peripheral membrane proteins, which are themselves positioned near the lipid bilayer by integral membrane proteins (see [Figure 10-31](#)). The resulting network creates a stiff cell cortex that provides mechanical support for the overlying plasma membrane, allowing the red blood cell to spring back to its original shape after squeezing through a capillary. Close relatives of spectrin are found in the cortex of most other vertebrate cell types, where they also help to shape and stiffen the surface membrane.

Any cross-linking protein that has its two actin-binding domains joined by a long bent linkage can form three-dimensional actin gels. *Filamin* (see [Figure 16-39](#)) promotes the formation of a loose and highly viscous gel by clamping together two actin filaments roughly at right angles ([Figure 16-42](#)). The actin gels formed by filamin are required for cells to extend the thin sheet-like membrane projections called *lamellipodia* that help them to crawl across solid surfaces. Filamin is lacking in some types of cancer cells, especially some malignant melanomas (pigment-cell cancers). These cells cannot crawl properly, and instead they protrude disorganized membrane blebs ([Figure 16-43](#)). Losing filamin is bad news for the melanoma cells but good news for the melanoma patient; because of the cells' inability to crawl, melanoma cells that have lost filamin expression are less invasive than similar melanoma cells that still express filamin, and, as a result, the cancer is much less likely to metastasize. [↑ TOP](#)

Severing Proteins Regulate the Length and Kinetic Behavior of Actin Filaments and Microtubules

In some situations, a cell may break an existing long filament into many

smaller filaments. This generates a large number of new filament ends: one long filament with just one plus end and one minus end might be broken into dozens of short filaments, each with its own minus end and plus end. Under some intracellular conditions, these newly formed ends nucleate filament elongation, and in this case severing accelerates the assembly of new filament structures. Under other conditions, severing promotes the depolymerization of old filaments, speeding up the depolymerization rate by tenfold or more (Figure 16-44). In addition, severing filaments changes the physical and mechanical properties of the cytoplasm: stiff, large bundles and gels become more fluid when the filaments are severed.

To sever a microtubule, thirteen longitudinal bonds must be broken, one for each protofilament. The protein *katanin*, named after the Japanese word for "sword," accomplishes this demanding task (Figure 16-45). Katanin is made up of two subunits, a smaller subunit that hydrolyzes ATP and performs the actual severing, and a larger one that directs katanin to the centrosome. Katanin releases microtubules from their attachment to a microtubule organizing center, and it is thought to have a particularly crucial role in the rapid microtubule depolymerization observed at the poles of a mitotic spindle during mitosis. It is also found in proliferating cells in interphase and in postmitotic cells such as neurons, where it may also be involved in microtubule release and depolymerization.

In contrast to microtubule severing by katanin, which requires ATP, the severing of actin filaments does not require an extra energy input. Most actin-severing proteins are members of the *gelsolin superfamily*, whose severing activity is activated by high levels of cytosolic Ca^{2+} . Gelsolin has subdomains that bind to two different sites on the actin subunit, one exposed on the surface of the filament and one that is normally hidden in the longitudinal bond to the next subunit in the protofilament. According to one model for gelsolin severing, gelsolin binds on the side of an actin filament and waits until a thermal fluctuation happens to create a small gap between neighboring subunits in the protofilament; gelsolin then insinuates its subdomain into the gap, breaking the filament (Figure 16-46). Once gelsolin has severed an actin filament, it remains bound to the plus end and acts as an effective capping protein. However, like several other actin filament capping proteins, it can be removed from the filament end by a local rise in PIP_2 concentration.

The process of platelet activation shows how a cell can regulate its actin accessory proteins that mediate severing, capping, and cross-linking to generate rapid and dramatic morphological changes. Platelets are tiny cells without a nucleus that circulate in the blood and help to form clots at sites of injury. The resting platelet is discoid in shape, and it contains short actin filaments capped by CapZ, surrounded by a large pool of actin monomer bound to profilin. When the platelet is activated by physical contact with the edge of a damaged blood vessel or by a chemical clotting signal such as thrombin, a rapid, intracellular, signal transduction cascade results in a massive

influx of Ca^{2+} into the platelet cytosol. The Ca^{2+} activates gelsolin, which cleaves the capped filaments into tiny fragments, each now capped by gelsolin. With slower kinetics, the same signaling pathway causes a rise in PIP_2 levels, which inactivates both gelsolin and CapZ, removing them from the filament plus ends. The large numbers of free plus ends generated by severing and uncapping are then rapidly elongated by the monomeric actin pool, forming many long filaments. Some of these long actin filaments are cross-linked into a gel by filamin, while others are bundled by α -actinin and fimbrin. This causes the activated platelet to extend lamellipodia and filopodia and to spread itself across the clot ([Figure 16-47](#)), attaching to the clot by transmembrane adhesion proteins called integrins. Once the PIP_2 signal subsides, the CapZ returns to the ends of the filaments, rendering them stable against depolymerization and locking the platelet into its spread form. Finally, myosin II uses ATP hydrolysis to slide the long actin filaments relative to one another, causing a contraction of the platelet that pulls the edges of the wound together. [↑ TOP](#)

Cytoskeletal Elements Can Attach to the Plasma Membrane

A common function of actin cytoskeletal structures is to stiffen or to change the shape of the plasma membrane. We have already encountered at least two examples: the spectrin-actin web that underlies the red blood cell plasma membrane and the villin-actin bundles in microvilli that enlarge the absorptive surface area of epithelial cells. The effectiveness of these structures depends on both the bundling and cross-linking of actin filaments and the specific attachments between the actin filament structures and proteins or lipids of the plasma membrane. In many cases, the cytoskeletal assemblies have the additional function of helping to connect the internal structure of a cell to its surrounding environment, including other cells and the extracellular matrix. Both actin filaments and intermediate filaments are critical for these connections. Here, we describe several types of specific interactions between cytoskeletal filaments and the transmembrane proteins that mediate cell adhesion. We consider only the intracellular side of these interactions; the extracellular interactions are discussed in [Chapter 19](#).

A widespread family of closely related intracellular proteins, the *ERM* family (named for its first three members, ezrin, radixin, and moesin), acts to attach actin filaments to the plasma membrane in many cell types. The C-terminal domain of ERM proteins binds directly to the sides of actin filaments. The N-terminal domain binds to the cytoplasmic face of several transmembrane glycoproteins, including CD44, the receptor for the extracellular matrix component hyaluronan. The functional importance of the ERM proteins is indicated by the consequences of mutations that lead to a loss of one of the members of the family, called merlin. This results in one form of the human genetic disease called *neurofibromatosis*, in which multiple benign tumors develop in the auditory nerves and certain other parts of the nervous system.

Unlike the attachments between actin and the plasma membrane mediated by

spectrin or myosin I, those mediated by ERM proteins are regulated by both intracellular and extracellular signals. ERM proteins can exist in two conformations, an active extended conformation that oligomerizes and binds actin and CD44, and an inactive folded conformation, in which the N- and C-termini are held together by an intramolecular interaction. Switching between the two conformations can be triggered by phosphorylation or binding to PIP₂, either of which can occur, for example, in response to extracellular signals. Thus, the strength of ERM-mediated contacts between the actin cytoskeleton and the extracellular matrix is sensitive to a variety of signals received by the cell (Figure 16-48). [↑ TOP](#)

Special Bundles of Cytoskeletal Filaments Form Strong Attachments Across the Plasma Membrane: Focal Contacts, Adhesion Belts, and Desmosomes

Focal contacts are a highly specialized type of attachment between actin filaments and the extracellular matrix that allows cells to pull on the substratum to which they are bound. Focal contacts are particularly easy to see in cultured fibroblasts, because they create spots where the normal 50 nm gap between the bottom of the cell and the substratum is reduced to only 10–15 nm (Figure 16-49). At these sites, stress fibers, consisting of contractile bundles of actin and myosin II filaments, terminate at the plasma membrane, where clusters of transmembrane adhesion proteins, called *integrins*, are located. Integrins are a large family of heterodimeric proteins that bind to various components of the extracellular matrix (discussed in Chapter 19), and their linkage to the bundle of actin filaments is indirect, being mediated by an elaborate complex composed of multiple intracellular anchor proteins.

Besides serving as anchors for the cell, focal contacts can also relay signals from the extracellular matrix to the inside of the cell. Thus, the clustering of integrins at focal contacts activates a tyrosine kinase, *focal adhesion kinase* (FAK) (discussed in Chapter 19). Its activity is sensitive to the type of substratum on which the cell rests, and it is also regulated by the amount of tension at the cell attachment site. How this occurs is uncertain, but FAK is a target of the Src cytoplasmic tyrosine kinase (discussed in Chapter 5), which is also enriched at focal contacts. Once activated, FAK phosphorylates numerous targets, including many components of the focal contact complex itself, and it thereby helps to regulate the survival, growth, proliferation, morphology, movement, and differentiation of cells in response to the extracellular environment. Although we know few of the details, it is possible that the growth and development of a cell are influenced as much by signals received by means of its adhesion proteins as by the more extensively studied receptors for soluble, extracellular signal molecules described in Chapter 15.

Besides forming mechanically strong attachments to the extracellular matrix, cytoskeletal elements anchored to the plasma membrane also provide

attachments to other cells. For example, the cell-cell contacts formed in epithelia are mediated largely by the interactions of transmembrane *cadherin* proteins (see [Figure 19-24](#)). The cytoplasmic tail of a cadherin molecule binds a complex of proteins called catenins, which in turn bind to actin filaments (see [Figure 19-29](#)). Clusters of these actin-reinforced, cadherin-mediated cell-cell contacts form the *adherens junctions* described in [Chapter 19](#).

The general principle that we see in focal contacts and adherens junctions, in which bundles of cytoskeletal filaments are indirectly attached through elaborate multiprotein complexes to transmembrane adhesion proteins, is recapitulated in the attachment of intermediate filaments to the plasma membrane. Intermediate filaments are anchored to the plasma membrane at structures called *desmosomes* (at cell-cell junctions) and *hemidesmosomes* (at cell-extracellular matrix junctions). These cell junctions are especially important in maintaining the strength of epithelial tissues (discussed in [Chapter 19](#)).  [TOP](#)

Extracellular Signals Can Induce Major Cytoskeletal Rearrangements

In the preceding sections, we have seen how accessory proteins associated with cytoskeletal filament systems can regulate filament length, location, organization, and dynamic behavior. Extracellular signals can alter the activity of these accessory proteins, thereby changing the cytoskeleton and cell behavior.

For the actin cytoskeleton, global structural rearrangements in response to external signals are triggered through diverse cell-surface receptors. But all of these signals seem to converge inside the cell on a group of closely related monomeric GTPases that are members of the **Rho protein family**—*Cdc42*, *Rac*, and *Rho*. Like other members of the Ras superfamily, these Rho proteins act as molecular switches to control cellular processes by cycling between an active, GTP-bound state and an inactive, GDP-bound state (see [Figure 3-70](#)). Activation of *Cdc42* triggers actin polymerization and bundling to form either filopodia or shorter cell protrusions called microspikes. Activation of *Rac* promotes actin polymerization at the cell periphery leading to the formation of sheet-like lamellipodial extensions and membrane ruffles. Activation of *Rho* promotes both the bundling of actin filaments with myosin II filaments into stress fibers and the clustering of integrins and associated proteins to form focal contacts ([Figure 16-50](#)). These dramatic and complex structural changes occur because each of these three molecular switches has numerous downstream target proteins that affect actin organization and dynamics (at least eight have been found for each). Other target proteins affect gene transcription.

Some key targets of activated *Cdc42* are members of the WASp protein family. **WASp proteins**, like ERM family proteins, can exist in an inactive

folded conformation and an activated open conformation. Association with Cdc42-GTP stabilizes the open form of WASp, enabling it to bind to the ARP complex. This strongly enhances the actin-nucleating activity of the ARP complex (see [Figure 16-28](#)). Thus, activation of Cdc42 causes an increase in actin nucleation. Rac-GTP also activates WASp family members, but in addition it activates PI(4)P-5 kinase, which generates PI(4,5)P₂ (a form of PIP₂). As we have seen previously, PIP₂ can cause the uncapping of filaments whose plus end is bound by gelsolin or CapZ, thereby providing even more sites for actin assembly near the plasma membrane, resulting in the formation of large lamellipodia and ruffles. Rho-GTP activates a protein kinase that inhibits a phosphatase acting on myosin light chains (see [Figure 16-67](#)). The consequent increase in the net amount of myosin light chain phosphorylation increases the amount of contractile myosin activity in the cell, enhancing the formation of tension-dependent structures such as stress fibers.

The mechanisms that turn on the three Rho protein family members are similarly complex. Their activation, through an exchange of GTP for GDP, is promoted by guanine nucleotide exchange factors (GEFs), of which more than 20 have been identified. Some are specific for an individual Rho family GTPase, whereas others seem to act on all three. Upstream from the GEFs are various cell-surface receptors. In most cases, the mechanisms that couple the receptors to GEF activation are unknown. [↑ TOP](#)

Summary

The varied forms and functions of cytoskeletal filament structures in eucaryotic cells depend on a versatile repertoire of accessory proteins. Each of the three major filament classes (microtubules, intermediate filaments, and actin filaments) has a large dedicated subset of such accessory proteins. A primary determinant of the sites of cytoskeletal structures is the regulation of the processes that initiate the nucleation of new filaments. In most animal cells, microtubules are nucleated at the centrosome, a complex assembly located near the center of the cell. In contrast, most actin filaments are nucleated near the plasma membrane.

The kinetics of filament assembly and disassembly can be either slowed or accelerated by accessory proteins that bind to either the free subunits or the filaments themselves. Some of these proteins alter filament dynamics by binding to the ends of filaments or by severing the filaments into smaller fragments. Another class of accessory proteins assembles the filaments into larger ordered structures by cross-linking them to one another in geometrically defined ways. Yet other accessory proteins determine the shape and adhesive properties of cells by attaching filaments to the plasma membrane. Cytoskeletal rearrangements are mediated by controlling the activities of various accessory proteins. [↑ TOP](#)

Figure 16-23. The centrosome. (A) The centrosome is the major MTOC of animal cells. Located in the cytoplasm next to the nucleus, it consists of an amorphous matrix of protein containing the γ -tubulin ring complexes that nucleate microtubule growth. This matrix is organized by a pair of centrioles, as described in the text. (B) A centrosome with attached microtubules. The minus end of each microtubule is embedded in the centrosome, having grown from a γ -tubulin ring complex, whereas the plus end of each microtubule is free in the cytoplasm.

Figure 16-25. The center-seeking behavior of a centrosome. (A) Small square wells were micromachined into a plastic substrate. A single centrosome was placed into one of these wells, along with tubulin subunits in solution. As the microtubules polymerize, nucleated by the centrosome, they push against the walls of the well. The requirement for equal pushing in all directions if the position is to be stabilized forces the centrosome to the center of the well. The three pictures were taken at three-minute intervals. (B) A similar self-centered centrosome, fixed and stained to show the distribution of the microtubules pushing on all four walls of the enclosure. (From T.E. Holy et al., *Proc. Natl. Acad. Sci. Figure 16-27. The tip of the leading edge of a cell nucleates actin filaments.

Fibroblasts in culture were gently permeabilized using a nonionic detergent and were then incubated with rhodamine-labeled actin molecules to visualize newly formed actin filaments (*red*). After 5 minutes, the cells were fixed and stained with fluorescein-labeled phalloidin to stain all actin filaments (*green*). (A) All of the actin filaments, most of which were formed before the cells were permeabilized, are shown in *green*. (B) The location of the newly formed actin filaments (*red*) show that the leading edge is the predominant site of actin filament assembly in the cell. Further studies show that this is because new actin filaments are constantly being nucleated here. (From M.H. Symons and T. J. Mitchison, *J. Cell Biol.* 114:503–513, 1991. © The Rockefeller University Press.)

Figure 16-28. Nucleation and actin web formation by the ARP complex. (A) The structures of Arp2 and Arp3, compared to the structure of actin. Although the face of the molecule equivalent to the plus end (*top*) in both Arp2 and Arp3 is very similar to the plus end of actin itself, differences on the sides and minus end (*bottom*) prevent these actin-related proteins from forming filaments on their own or coassembling into filaments with actin. (B) A model for actin filament nucleation by the ARP complex. Arp2 and Arp3 may be held by their accessory proteins in an orientation that resembles the plus end of an actin filament. Actin subunits can then assemble onto this structure, bypassing the rate-limiting step of filament nucleation (see Figure 16-5). (C) The ARP complex nucleates filaments more efficiently when it is bound to the side of a preexisting actin filament. The result is a filament branch that grows at a 70° angle relative to the original filament. Repeated rounds of branching nucleation result in a treelike web of actin filaments. (D) Electron micrographs of branched actin filaments formed by mixing purified actin subunits with purified ARP complexes. (D, courtesy of R.D. Mullins et al., *Proc. Natl. Acad. Sci. USA* 95:6181–6186, 1998. © National Academy of Sciences.)

Figure 16-30. Effects of thymosin and profilin on actin polymerization. An actin monomer bound to thymosin is sterically prevented from binding to and elongating the plus end of an actin filament. An actin monomer bound to profilin, on the other hand, is capable of elongating a filament. Thymosin and profilin cannot both bind to a single actin monomer at the same time. In a cell in which most of the actin monomer is bound to thymosin, the activation of a small amount of profilin can produce rapid filament assembly. As indicated, profilin binds to actin monomers that are transiently released from the thymosin-bound monomer pool, shuttles them onto the plus ends of actin filaments, and is then released and recycled for further rounds of filament elongation.

Figure 16-31. Effects of stathmin on microtubule polymerization. Polymerization of free tubulin subunits to form microtubules is an energetically favorable reaction. As long as abundant free tubulin subunits are available, microtubule elongation continues. Stathmin sequesters free tubulin subunits, binding two tubulin $\alpha\beta$ -heterodimers per stathmin molecule. As the pool of free tubulin subunits shrinks, microtubule elongation slows. This makes it more likely that the rate of GTP hydrolysis will catch up with the rate of subunit addition, and the GTP cap will be lost, resulting in a transition of the microtubule from the growing state to the shrinking state. Stathmin has a second activity that promotes this transition, which involves a direct interaction with a microtubule plus end (not shown). Stathmin is also called "oncoprotein 18," since its expression level is frequently increased in tumor cells, resulting in increased turnover of microtubules.

Figure 16-34. Twisting of an actin filament induced by cofilin. (A) Three-dimensional reconstruction from cryo-electron micrographs of filaments made of pure actin. The bracket shows the span of two turns of the actin helix. (B) Reconstruction of an actin filament coated with cofilin, which binds in a 1:1 stoichiometry to actin subunits all along the filament. Cofilin is a small protein (14 kilodaltons) compared to actin (43 kilodaltons), and so the filament appears only slightly thicker. The energy of cofilin binding serves to deform the actin filament lattice, twisting it more tightly so that the distance spanned by two turns of the helix is reduced. (From A. McGough et al., *J. Cell Biol.* 138:771–781, 1997. © The Rockefeller University Press.)

Figure 16-35. Filament capping and its effects on filament dynamics. A population of uncapped filaments adds and loses subunits at both the plus and minus ends, resulting in rapid growth or shrinkage, depending on the concentration of available free monomers (*green line*). In the presence of a protein that caps the plus end (*red line*), only the minus end is able to add or lose subunits; consequently, filament growth will be slower at all monomer concentrations above the critical concentration, and filament shrinkage will be slower at all monomer concentrations below the critical concentration. Plus-end capping of this type is widely used for actin filaments but not for microtubules.

Figure 16-36. The effects of proteins that bind to microtubule ends. (A) The transition between microtubule growth and microtubule shrinking is controlled in cells by special proteins. A MAP such as XMAP215 stabilizes the end of a growing microtubule by its preferential binding there. Opposing its action are members of the kinesin superfamily (discussed later) designated here as catastrophins, but called by a variety of other names (such as, the Kin1 family that includes KIF2 in [Figure 16-55](#)). (B) Capping proteins help to localize microtubules. Here, the EB1 microtubule capping protein interacts with localized Kar9 proteins in the budding yeast *Saccharomyces cerevisiae*. This interaction directs spindle microtubules into the growing bud during mitosis. A mutation in either protein causes the indicated spindle

microtubules to lose their way. The EB1 protein is also found on the plus ends of microtubules in human cells.

Figure 16-44. Filament severing and its effects on filament dynamics.

Normally, filaments are able to gain and lose subunits only at their ends, limiting the maximum rates of growth and shrinkage of the total amount of actin in filamentous form (*green line*). If the filaments are severed into smaller pieces, the number of ends increases, so the increase in filament mass in the population can be faster at all monomer concentrations above the critical concentration, and the decrease in filament mass in the population can also be faster at all monomer concentrations below the critical concentration (*red line*). Thus, severing enhances the rate of filament dynamics.

Figure 16-46. A model for actin filament severing by gelsolin. There are two actin-binding sites in the gelsolin protein. These sites allow gelsolin to bind both along the side and at the end of an actin filament. Filaments that have been severed by gelsolin remain capped at their plus ends. Villin, an actin-bundling protein (see [Figure 16-41A](#)), is a member of the same protein family as gelsolin, but it has gained another actin-binding site and lost its ability to sever filaments except at very high (nonphysiological) Ca^{2+} concentrations.

Figure 16-50. The dramatic effects of Rac, Rho, and Cdc42 on actin organization in fibroblasts. In each case, the actin filaments have been labeled with fluorescent phalloidin, and focal contacts have been located with an antibody against vinculin. (A) Serum-starved fibroblasts have actin filaments primarily in the cortex, and relatively few focal contacts. (B) Microinjection of a constitutively activated form of Rho causes the rapid assembly of many prominent stress fibers and focal contacts. (C) Microinjection of a constitutively activated form of Rac, a closely related monomeric GTPase, causes the formation of an enormous lamellipodium that extends from the entire circumference of the cell. (D) Microinjection of a constitutively activated form of Cdc42, another Rho family member, causes the protrusion of many long filopodia at the cell periphery that form adhesive contacts with the substratum. The distinct global effects of these three GTPases on the organization of the actin cytoskeleton are mediated by the actions of dozens of other protein molecules that are regulated by the GTPases. Many of these target proteins resemble the various actin-associated proteins that we have discussed in this chapter. (From A. Hall, *Science* 279:509–514, 1998. © AAAS.)

Molecular Motors

Perhaps the most fascinating proteins that associate with the cytoskeleton are the molecular motors called motor proteins. These remarkable proteins bind to a polarized cytoskeletal filament and use the energy derived from repeated cycles of ATP hydrolysis to move steadily along it. Dozens of different motor proteins coexist in every eucaryotic cell. They differ in the type of filament they bind to (either actin or microtubules), the direction in which they move along the filament, and the "cargo" they carry. Many motor proteins carry membrane-enclosed organelles—such as mitochondria, Golgi stacks, or secretory vesicles—to their appropriate locations in the cell. Other motor proteins cause cytoskeletal filaments to slide against each other, generating the force that drives such phenomena as muscle contraction, ciliary beating, and cell division.

Cytoskeletal motor proteins that move unidirectionally along an oriented polymer track are reminiscent of some other proteins and protein complexes discussed elsewhere in this book, such as DNA and RNA polymerases, helicases, and ribosomes. All of these have the ability to use chemical energy to propel themselves along a linear track, with the direction of sliding dependent on the structural polarity of the track. All of them generate motion by coupling nucleoside triphosphate hydrolysis to a large-scale conformational change in a protein, as explained in [Chapter 3](#).

The cytoskeletal motor proteins associate with their filament tracks through a "head" region, or *motor domain*, that binds and hydrolyzes ATP. Coordinated with their cycle of nucleotide hydrolysis and conformational change, the proteins cycle between states in which they are bound strongly to their filament tracks and states in which they are unbound. Through a mechanochemical cycle of filament binding, conformational change, filament release, conformational relaxation, and filament rebinding, the motor protein and its associated cargo move one step at a time along the filament (typically a distance of a few nanometers). The identity of the track and the direction of movement along it are determined by the motor domain (head), while the identity of the cargo (and therefore the biological function of the individual motor protein) is determined by the tail of the motor protein.

In this section, we begin by describing the three groups of cytoskeletal motor proteins. We then describe how they work to transport membrane-enclosed organelles or to change the shape of structures built from cytoskeletal filaments. We end by describing their action in muscle contraction and in powering the whiplike motion of structures formed from microtubules.

Actin-based Motor Proteins Are Members of the Myosin Superfamily

The first motor protein identified was skeletal muscle **myosin**, which is responsible for generating the force for muscle contraction. This myosin, called *myosin II* (see below) is an elongated protein that is formed from two heavy chains and two copies of each of two light chains. Each of the heavy chains has a globular head domain at its N-terminus that contains the force-generating machinery, followed by a very long amino acid sequence that forms an extended coiled-coil that mediates heavy chain dimerization ([Figure 16-51](#)). The two light chains bind close to the N-terminal head domain, while the long coiled-coil tail bundles itself with the tails of other myosin molecules. These tail-tail interactions result in the formation of large bipolar "thick filaments" that have several hundred myosin heads, oriented in opposite directions at the two ends of the thick filament ([Figure 16-52](#)).

Each myosin head binds and hydrolyses ATP, using the energy of ATP hydrolysis to walk toward the plus end of an actin filament. The opposing orientation of the heads in the thick filament makes the filament efficient at sliding pairs of oppositely oriented actin filaments past each other. In skeletal muscle, in which carefully arranged actin filaments are aligned in "thin filament" arrays surrounding the myosin thick filaments, the ATP-driven sliding of actin filaments results in muscle contraction (discussed later). Cardiac and smooth muscle contain myosins that are similarly arranged, although they are encoded by different genes.

When a muscle myosin is digested by chymotrypsin and papain, the head domain is released as an intact fragment (called S1). The S1 fragment alone can generate filament sliding *in vitro*, proving that the motor activity is contained completely within the head ([Figure 16-53](#)).

It was initially thought that myosin was present only in muscle, but in the 1970's, researchers found that a similar two-headed myosin protein was also present in nonmuscle cells, including protozoan cells. At about the same time, other researchers found a myosin in the freshwater amoeba *Acanthamoeba castellanii* that was unconventional in having a motor domain similar to the head of muscle myosin but a completely different tail. This molecule seemed to function as a monomer and was named *myosin I* (for one-headed); the conventional myosin was renamed *myosin II* (for two-headed).

Subsequently, many other myosin types were discovered. The heavy chains

generally start with a recognizable myosin motor domain at the N-terminus, and then diverge widely with a variety of C-terminal tail domains (Figure 16-54). The new types of myosins include a number of one-headed and two-headed varieties that are approximately equally related to myosin I and myosin II, and the nomenclature now reflects their approximate order of discovery (myosin III through at least myosin XVIII). The myosin tails (and the tails of motor proteins generally) have apparently diversified during evolution to permit the proteins to dimerize with other subunits and to interact with different cargoes.

Some myosins (such as VIII and XI) have been found only in plants, and some have been found only in vertebrates (IX). Most, however, are found in all eucaryotes, suggesting that myosins arose early in eucaryotic evolution. The yeast *Saccharomyces cerevisiae* contains five myosins: two myosin Is, one myosin II, and two myosin Vs. One can speculate that these three types of myosins are necessary for a eucaryotic cell to survive and that other myosins perform more specialized functions in multicellular organisms. The nematode *C. elegans*, for example, has at least 15 myosin genes, representing at least seven structural classes; the human genome includes about 40 myosin genes.

All of the myosins except one move toward the plus end of an actin filament, although they do so at different speeds. The exception is myosin VI, which moves toward the minus end.

The exact functions for most of the myosins remain to be determined. Myosin II is always associated with contractile activity in muscle and nonmuscle cells. It is also generally required for cytokinesis, the pinching apart of a dividing cell into two daughters (discussed in Chapter 18), as well as for the forward translocation of the body of a cell during cell migration. The myosin I proteins contain a second actin-binding site or a membrane-binding site in their tails, and they are generally involved in intracellular organization and the protrusion of actin-rich structures at the cell surface. Myosin V is involved in vesicle and organelle transport. Myosin VII is found in the inner ear in vertebrates, and certain mutations in the gene coding for myosin VII cause deafness in mice and humans. [↑ TOP](#)

There Are Two Types of Microtubule Motor Proteins: Kinesins and Dyneins

Kinesin is a motor protein that moves along microtubules. It was first identified in the giant axon of the squid, where it carries membrane-enclosed organelles away from the neuronal cell body toward the axon terminal by walking toward the plus end of microtubules. Kinesin is similar structurally to myosin II in having two heavy chains and two light chains per active motor, two globular head motor domains, and an elongated coiled-coil responsible for heavy chain dimerization. Like myosin, kinesin is a member of a large protein superfamily, for which the motor domain is the only common element (Figure

Search

books

All

PubMed

16-55). The yeast *Saccharomyces cerevisiae* has six distinct kinesins. The nematode *C. elegans* has 16 kinesins, and humans have about 40.

There are at least ten families of **kinesin-related proteins**, or **KRPs**, in the kinesin superfamily. Most of them have the motor domain at the N-terminus of the heavy chain and walk toward the plus end of the microtubule. A particularly interesting family has the motor domain at the C-terminus and walks in the opposite direction, toward the minus end of the microtubule. Some KRP heavy chains lack a coiled-coil sequence and seem to function as monomers, analogous to myosin I. Some others are homodimers, and yet others are heterodimers. At least one KRP (BimC) can self-associate through the tail domain, forming a bipolar motor that slides oppositely oriented microtubules past one another, much as a myosin II thick filament does for actin filaments. Most kinesins carry a binding site in the tail for either a membrane-enclosed organelle or another microtubule. Many of the kinesin superfamily members have specific roles in mitotic and meiotic spindle formation and chromosome separation during cell division.

The dyneins are a family of minus-end-directed microtubule motors, but they are unrelated to the kinesin superfamily. They are composed of two or three heavy chains (that include the motor domain) and a large and variable number of associated light chains. The dynein family has two major branches (Figure 16-56). The most ancient branch contains the *cytoplasmic dyneins*, which are typically heavy-chain homodimers, with two large motor domains as heads. Cytoplasmic dyneins are probably found in all eucaryotic cells, and they are important for vesicle trafficking, as well as for localization of the Golgi apparatus near the center of the cell. *Axonemal dyneins*, the other large branch, include heterodimers and heterotrimers, with two or three motor-domain heads, respectively. They are highly specialized for the rapid and efficient sliding movements of microtubules that drive the beating of cilia and flagella (discussed later). A third, minor, branch shares greater sequence similarity with cytoplasmic than with axonemal dyneins but seems to be involved in the beating of cilia.

Dyneins are the largest of the known molecular motors, and they are also among the fastest: axonemal dyneins can move microtubules in a test tube at the remarkable rate of 14 $\mu\text{m}/\text{sec}$. In comparison, the fastest kinesins can move their microtubules at about 2–3 $\mu\text{m}/\text{sec}$. [↑ TOP](#)

The Structural Similarity of Myosin and Kinesin Indicates a Common Evolutionary Origin

The motor domain of myosins is substantially larger than that of kinesins, about 850 amino acids compared with about 350. The two classes of motor proteins track along different filaments and have different kinetic properties, and they have no identifiable amino acid sequence similarities. However, determination of the three-dimensional structure of the motor domains of

myosin and kinesin has revealed that these two motor domains are built around nearly identical cores ([Figure 16-57](#)). The central force-generating element that the two types of motor proteins have in common includes the site of ATP binding and the machinery necessary to translate ATP hydrolysis into an allosteric conformational change. The differences in domain size and in the choice of track can be attributed to large loops extending outward from this central core. These loops include the actin-binding and microtubule-binding sites, respectively.

An important clue to how the central core is involved in force generation has come from the observation that the motor core also bears some structural resemblance to the nucleotide binding site of the small GTPases of the Ras superfamily. As discussed in [Chapter 3](#) (see [Figure 3-74](#)), these proteins exhibit distinct conformations in their GTP-bound (active) and GDP-bound (inactive) forms: mobile "switch" loops in the nucleotide-binding site are in close contact with the γ -phosphate in the GTP-bound state, but these loops swing out when the hydrolyzed γ -phosphate is released. Although the details of the movement are different for the two motor proteins, and ATP rather than GTP is hydrolyzed, the relatively small structural change in the active site—the presence or absence of a terminal phosphate—is similarly amplified to cause a rotation of a different part of the protein. In kinesin and myosin, a switch loop interacts extensively with those regions of the protein involved in microtubule and actin binding, respectively, allowing the structural transitions caused by the ATP hydrolysis cycle to be relayed to the polymer-binding interface. The relay of structural changes between the polymer-binding site and the nucleotide hydrolysis site seems to work in both directions, since the ATPase activity of motor proteins is strongly activated by binding to their filament tracks. [↑ TOP](#)

Motor Proteins Generate Force by Coupling ATP Hydrolysis to Conformational Changes

Although the cytoskeletal motor proteins and GTP-binding proteins both use structural changes in their nucleoside-triphosphate-binding sites to produce cyclic interactions with a partner protein, the motor proteins have a further requirement: each cycle of binding and release must propel them forward in a single direction along a filament to a new binding site on the filament. For such unidirectional motion, a motor protein must use the energy derived from ATP binding and hydrolysis to force a large movement in part of the protein molecule. For myosin, each step of the movement along actin is generated by the swinging of an 8.5-nm-long α helix, or *lever arm* (see [Figure 16-57](#)), which is structurally stabilized by the binding of light chains. At the base of this lever arm next to the head, there is a piston-like helix that connects movements at the ATP-binding cleft in the head to small rotations of the so-called converter domain. A small change at this point can swing the helix like a long lever, causing the far end of the helix to move by about 5.0 nm. These changes in the conformation of the myosin are coupled to changes in its

binding affinity for actin, allowing the myosin head to release its grip on the actin filament at one point and snatch hold of it again at another. The full mechanochemical cycle of nucleotide binding, nucleotide hydrolysis, and phosphate release (which causes the "power stroke") produces a single step of movement ([Figure 16-58](#)). In the myosin VI subfamily of myosins, which move backward (toward the minus end of the actin filament), the converter domain probably lies in a different orientation, so that the same piston-like movement of the small helix causes the lever arm to rotate in the opposite direction.

In kinesin, instead of the rocking of a lever arm, the small movements of switch loops at the nucleotide-binding site regulate the docking and undocking of the motor head domain to a long linker region that connects this motor head at one end to the coiled-coil dimerization domain at the other end. When the front (leading) kinesin head is bound to a microtubule before the power stroke, its linker region is relatively unstructured. On the binding of ATP to this bound head, its linker region docks along the side of the head, which throws the second head forward to a position where it will be able to bind a new attachment site on the protofilament, 8 nm closer to the microtubule plus end than the binding site for the first head. The nucleotide hydrolysis cycles in the two heads are closely coordinated, so that this cycle of linker docking and undocking can allow the two-headed motor to move in a hand-over-hand (or head-over-head) stepwise manner ([Figure 16-59A](#)).

The coiled-coil domain seems both to coordinate the mechanochemical cycles of the two heads (motor domains) of the kinesin dimer and to determine its directionality of movement. Recall that whereas most members of the kinesin superfamily, with their motor domains at the N-terminus, move toward the plus end of the microtubule, a few superfamily members have their motor domains at the C-terminus and move toward the minus end. Since the motor domains of these two types of kinesins are essentially identical, how can they move in opposite directions? The answer seems to lie in the way in which the heads are connected. In high-resolution images of forward-walking and backward-walking members of the kinesin superfamily bound to microtubules, the heads that are attached to the microtubule are essentially indistinguishable, but the second, unattached heads are oriented very differently. This difference in tilt apparently biases the next binding site for the second head, and thereby determines the directionality of motor movement ([Figure 16-60](#)).

Although both myosin and kinesin undergo analogous mechanochemical cycles, the exact nature of the coupling between the mechanical and chemical cycles is different in the two cases (see [Figure 16-60](#)). For example, myosin without any nucleotide is tightly bound to its actin track, in a so-called "rigor" state, and it is released from this track by the association of ATP. In contrast, kinesin forms a rigor-like tight association with a microtubule when ATP is bound to the kinesin, and it is hydrolysis of ATP that promotes release of the motor from its track.

Thus, cytoskeletal motor proteins work in a manner highly analogous to GTP-binding proteins, except that in motor proteins the small protein conformational changes (a few tenths of a nanometer) associated with nucleotide hydrolysis are amplified by special protein domains—the lever arm in the case of myosin and the linker in the case of kinesin—to generate large-scale (several nanometers) conformational changes that move the motor proteins stepwise along their filament tracks. The analogy between the GTPases and the cytoskeletal motor proteins has recently been extended by the observation that one of the GTP-binding proteins—the bacterial elongation factor G—translates the chemical energy of GTP hydrolysis into directional movement of the mRNA molecule on the ribosome. [↑ TOP](#)

Motor Protein Kinetics Are Adapted to Cell Functions

The motor proteins in the myosin and kinesin superfamilies exhibit a remarkable diversity of motile properties, well beyond their choice of different polymer tracks. Most strikingly, a single dimer of conventional kinesin moves in a highly processive fashion, traveling for hundreds of ATPase cycles along a microtubule without dissociating. Skeletal muscle myosin II, in contrast, cannot move processively and makes just one or a few steps along an actin filament before letting go. These differences are critical for the motors' various biological roles. A small number of kinesin molecules must be able to transport a mitochondrion all the way down a nerve cell axon, and therefore require a high level of processivity. Skeletal muscle myosin, in contrast, never operates as a single molecule but rather as part of a huge array of myosin II molecules. Here processivity would actually inhibit biological function, since efficient muscle contraction requires that each myosin head perform its power stroke and then quickly get out of the way, to avoid interfering with the actions of the other heads attached to the same actin filament.

There are two reasons for the high degree of processivity of kinesin movement. The first is that the mechanochemical cycles of the two motor heads in a kinesin dimer are coordinated with each other, so that one kinesin head does not let go until the other is poised to bind. This coordination allows the motor protein to operate in a hand-over-hand fashion, never allowing the organelle cargo to diffuse away from the microtubule track. There is no apparent coordination between the myosin heads in a myosin II dimer. The second reason for the high processivity of kinesin movement is that kinesin spends a relatively large fraction of its ATPase cycle tightly bound to the microtubule. For both kinesin and myosin, the conformational change that produces the force-generating working stroke must occur while the motor protein is tightly bound to its polymer, and the recovery stroke in preparation for the next step must occur while the motor is unbound. But as we have seen in [Figure 16-59](#), myosin spends only about 5% of its ATPase cycle in the tightly bound state and is unbound the rest of the time.

What myosin loses in processivity it gains in speed; in an array in which many motor heads are interacting with the same actin filament, a set of linked

myosins can move their filament a total distance equivalent to 20 steps during a single cycle time, while kinesins can move only two. Thus, myosins can typically drive filament sliding much more rapidly than kinesins, even though they hydrolyze ATP at comparable rates and take molecular steps of comparable length.

Within each motor protein class, movement speeds vary widely, from about 0.2 to 60 $\mu\text{m}/\text{sec}$ for myosins, and from about 0.02 to 2 $\mu\text{m}/\text{sec}$ for kinesins. These differences arise from a fine-tuning of the mechanochemical cycle. The number of steps that an individual motor molecule can take in a given time, and thereby the velocity, can be increased by either increasing the motor protein's intrinsic ATPase rate or decreasing the proportion of cycle time spent bound to the filament track. Moreover, the size of each step can be changed by either changing the length of the lever arm (for example, the lever arm of myosin V is about three times longer than the lever arm of myosin II) or the angle through which the helix swings (Figure 16-61). Each of these parameters varies slightly among different members of the myosin and kinesin families, corresponding to slightly different protein sequences and structures. It is assumed that the behavior of each motor protein, whose function is determined by the identity of the cargo attached through its tail-domain, has been fine-tuned during evolution for speed and processivity according to the specific needs of the cell. [↑ TOP](#)

Motor Proteins Mediate the Intracellular Transport of Membrane-enclosed Organelles

A major function of cytoskeletal motors in interphase cells is the transport and positioning of membrane-enclosed organelles. Kinesin was originally identified as the protein responsible for fast axonal transport, the rapid movement of mitochondria, secretory vesicle precursors, and various synapse components down the microtubule highways of the axon to the distant nerve terminals. Although organelles in most cells need not cover such long distances, their polarized transport is equally necessary. A typical microtubule array in an interphase cell is oriented with the minus ends near the center of the cell at the centrosome, and the plus ends extending to the cell periphery. Thus, centripetal movements of organelles toward the cell center require the action of minus-end-directed motor proteins such as cytoplasmic dynein, whereas centrifugal movements toward the periphery require plus-end-directed motors such as kinesins.

The role of microtubules and microtubule motors in the behavior of intracellular membranes is best exemplified by the part they play in organizing the endoplasmic reticulum (ER) and the Golgi apparatus. The network of ER membrane tubules aligns with microtubules and extends almost to the edge of the cell, whereas the Golgi apparatus is located near the centrosome. When cells are treated with a drug that depolymerizes microtubules, such as colchicine or nocodazole, the ER collapses to the center of the cell, while the

Golgi apparatus fragments and disperses throughout the cytoplasm ([Figure 16-62](#)). *In vitro*, kinesins can tether ER-derived membranes to preformed microtubule tracks, and walk toward the microtubule plus ends, dragging the ER membranes out into tubular protrusions and forming a membranous web very much like the ER in cells. Likewise, the outward movement of ER tubules toward the cell periphery is associated with microtubule growth in living cells. Conversely, dyneins are required for positioning the Golgi apparatus near the cell center, moving Golgi vesicles along microtubule tracks toward minus ends at the centrosome.

The different tails and their associated light chains on specific motor proteins allow the motors to attach to their appropriate organelle cargo. For example, there is evidence for membrane-associated motor receptors, sorted to specific membrane-enclosed compartments, that interact directly or indirectly with the tails of the appropriate kinesin family members. One of these receptors seems to be the amyloid precursor protein, APP, which binds directly to a light chain on the tail of kinesin-I and is proposed to be a transmembrane motor protein receptor molecule in nerve-cell axons. It is the abnormal processing of this protein that gives rise to Alzheimer's disease, as discussed in [Chapter 15](#).

For dynein, attachment to membranes is known to be mediated by a large macromolecular assembly. Cytoplasmic dynein is itself a huge protein complex, and it requires association with a second large protein complex called *dynactin* to translocate organelles effectively. The dynactin complex includes a short actinlike filament that is made of the actin-related protein Arp1 (distinct from Arp2 and Arp3, the components of the ARP complex involved in the nucleation of conventional actin filaments). Membranes of the Golgi apparatus are coated with the proteins ankyrin and spectrin, which have been proposed to associate with the Arp1 filament in the dynactin complex to form a planar cytoskeletal array reminiscent of the erythrocyte membrane cytoskeleton (see [Figure 10-31](#)). The spectrin array probably gives structural stability to the Golgi membrane, and—via the Arp1 filament—it may mediate the regulatable attachment of dynein to the organelle ([Figure 16-63](#)).

Motor proteins also have a significant role in organelle transport along actin filaments. The first myosin shown to mediate organelle motility was myosin V, a two-headed myosin with a large step size (see [Figure 16-61](#)). In mice, mutations in the myosin V gene result in a "dilute" phenotype, in which fur color looks faded. In mice (and humans), membrane-enclosed pigment granules, called *melanosomes*, are synthesized in cells called *melanocytes* beneath the skin surface. These melanosomes move out to the ends of dendritic processes in the melanocytes, from where they are delivered to the overlying keratinocytes that form the skin and fur. Myosin V is associated with the surface of melanosomes, and it is able to mediate their actin-based movement in a test tube ([Figure 16-64](#)). In dilute mutant mice, the melanosomes are not delivered to the keratinocytes efficiently, and pigmentation is defective. Other myosins, including myosin I, are associated with endosomes and a variety of

other organelles. [↑ TOP](#)

Motor Protein Function Can Be Regulated

The cell can regulate the activity of motor proteins, allowing it to change either the positioning of its membrane-enclosed organelles or its whole-cell movements. One of the most dramatic examples is provided by fish melanocytes. These giant cells, which are responsible for rapid changes in skin coloration in several species of fish, contain large pigment granules that can alter their location in response to neuronal or hormonal stimulation ([Figure 16-65](#)). These pigment granules aggregate or disperse by moving along an extensive network of microtubules. The minus ends of these microtubules are nucleated by the centrosome and are located in the center of the cell, while the plus ends are distributed around the cell periphery. The tracking of individual pigment granules reveals that the inward movement is rapid and smooth, while the outward movement is jerky, with frequent backward steps ([Figure 16-66](#)). Both dynein and kinesin are associated with the pigment granules. The jerky outward movements apparently result from a tug-of-war between the two motor proteins, with the stronger kinesin winning out overall. When the kinesin light chains become phosphorylated after a hormonal stimulation that signals skin color change, kinesin is inactivated, leaving dynein free to drag the pigment granules rapidly toward the cell center, changing the fish's color. In a similar way, the movement of other membrane organelles coated with particular motor proteins is controlled by a complex balance of competing signals that regulate both motor protein attachment and activity.

Myosin activity can also be regulated by phosphorylation. In nonmuscle cells, myosin II can be phosphorylated on a variety of sites on both heavy and light chains, affecting both motor activity and thick filament assembly. The myosin II can exist in two different conformational states in such cells, an extended state that is capable of forming bipolar filaments, and a bent state in which the tail domain apparently interacts with the motor head. Phosphorylation of the regulatory light chain by the calcium-dependent *myosin light-chain kinase* (*MLCK*) causes the myosin II to preferentially assume the extended state, which promotes its assembly into a bipolar filament and leads to cell contraction ([Figure 16-67](#)). Myosin light-chain phosphorylation is an indirect target of activated Rho, the small GTPase discussed previously whose activation causes a reorganization of the actin cytoskeleton into contractile stress fibers. The MLCK is also activated during mitosis, causing myosin II to assemble into the contractile ring that is responsible for dividing the mitotic cell into two. Regulation of other members of the myosin superfamily is not as well understood, but control of these myosins is also likely to involve site-specific phosphorylations. [↑ TOP](#)

Muscle Contraction Depends on the Sliding of Myosin II and Actin Filaments

Muscle contraction is the most familiar and the best understood form of movement in animals. In vertebrates, running, walking, swimming, and flying all depend on the rapid contraction of skeletal muscle on its scaffolding of bone, while involuntary movements such as heart pumping and gut peristalsis depend on the contraction of cardiac muscle and smooth muscle, respectively. All these forms of muscle contraction depend on the ATP-driven sliding of highly organized arrays of actin filaments against arrays of myosin II filaments.

Muscle was a relatively late evolutionary development, and muscle cells are highly specialized for rapid and efficient contraction. The long thin muscle fibers of skeletal muscle are actually huge single cells that form during development by the fusion of many separate cells, as discussed in [Chapter 22](#). The many nuclei of the contributing cells are retained in this large cell and lie just beneath the plasma membrane, but the bulk of the cytoplasm inside is made up of myofibrils, which is the name given to the basic contractile elements of the muscle cell ([Figure 16-68](#)). A [myofibril](#) is a cylindrical structure 1–2 μm in diameter that is often as long as the muscle cell itself. It consists of a long repeated chain of tiny contractile units—called *sarcomeres*, each about 2.2 μm long, which give the vertebrate myofibril its striated appearance ([Figure 16-69](#)).

Each sarcomere is formed from a miniature, precisely ordered array of parallel and partly overlapping thin and thick filaments. The *thin filaments* are composed of actin and associated proteins, and they are attached at their plus ends to a *Z disc* at each end of the sarcomere. The capped minus ends of the actin filaments extend in toward the middle of the sarcomere, where they overlap with *thick filaments*, the bipolar assemblies formed from specific muscle isoforms of myosin II (see [Figure 16-52](#)). When this region of overlap is examined in cross section by electron microscopy, the myosin filaments are seen to be arranged in a regular hexagonal lattice, with the actin filaments evenly spaced between them ([Figure 16-70](#)). Cardiac muscle and smooth muscle also contain sarcomeres, although the organization is not as regular as that in skeletal muscle.

Sarcomere shortening is caused by the myosin filaments sliding past the actin thin filaments, with no change in the length of either type of filament ([Figure 16-71](#)). Bipolar thick filaments walk toward the plus ends of two sets of thin filaments of opposite orientations, driven by dozens of independent myosin heads that are positioned to interact with each thin filament. There is no coordination among the movements of the myosin heads, so it is critical that they operate with a low processivity, remaining tightly bound to the actin filament for only a small fraction of each ATPase cycle so that they do not hold one another back. Each myosin thick filament has about 300 heads (294 in frog muscle), and each head cycles about five times per second in the course of a rapid contraction—sliding the myosin and actin filaments past one another at rates of up to 15 $\mu\text{m}/\text{sec}$ and enabling the sarcomere to shorten by 10% of its length in less than 1/50th of a second. The rapid synchronized

shortening of the thousands of sarcomeres lying end-to-end in each myofibril gives skeletal muscle the ability to contract rapidly enough for running and flying, and even for playing the piano.

Accessory proteins govern the remarkable uniformity in filament organization, length, and spacing in the sarcomere (Figure 16-72). As mentioned previously, the actin filament plus ends are anchored in the Z disc, which is built from CapZ and α -actinin; the Z disc caps the filaments (preventing depolymerization), while holding them together in a regularly spaced bundle. The precise length of each filament is determined by a template protein of enormous size, called *nebulin*, which consists almost entirely of a repeating 35-amino-acid actin-binding motif. Nebulin stretches from the Z disc to the minus end of each thin filament and acts as a "molecular ruler" to dictate the length of the filament. The minus ends of the thin filaments are capped and stabilized by tropomodulin. Thus, the actin filaments in sarcomeres are remarkably stable, unlike the dynamic actin filaments characteristic of most other cell types.

The thick filaments are positioned midway between the Z discs by opposing pairs of an even longer template protein, called *titin*. Titin acts as a molecular spring, with a long series of immunoglobulin-like domains that can unfold one by one as stress is applied to the protein. A springlike unfolding and refolding of these domains keeps the thick filaments poised in the middle of the sarcomere and allows the muscle fiber to recover after being overstretched. In *C. elegans*, whose sarcomeres are longer than those in vertebrates, titin is also longer, suggesting that it too serves as a molecular ruler, determining in this case the overall length of each sarcomere (see Figure 3-34). [↑ TOP](#)

Muscle Contraction Is Initiated by a Sudden Rise in Cytosolic Ca^{2+} Concentration

The force-generating molecular interaction between myosin thick filaments and actin thin filaments takes place only when a signal passes to the skeletal muscle from its motor nerve. The signal from the nerve triggers an action potential in the muscle cell plasma membrane (discussed in Chapter 11), and this electrical excitation spreads rapidly into a series of membraneous folds, the transverse tubules, or *T tubules*, that extend inward from the plasma membrane around each myofibril. The signal is then relayed across a small gap to the *sarcoplasmic reticulum*, an adjacent web-like sheath of modified endoplasmic reticulum that surrounds each myofibril like a net stocking (Figure 16-73A, B).

When voltage-sensitive proteins in the T-tubule membrane are activated by the incoming action potential, they trigger the opening of Ca^{2+} -release channels in the sarcoplasmic reticulum (Figure 16-73C). Ca^{2+} flooding into the cytosol then initiates the contraction of each myofibril. Because the signal from the muscle-cell plasma membrane is passed within milliseconds (via the T tubules

and sarcoplasmic reticulum) to every sarcomere in the cell, all of the myofibrils in the cell contract at the same time. The increase in Ca^{2+} concentration is transient because the Ca^{2+} is rapidly pumped back into the sarcoplasmic reticulum by an abundant, ATP-dependent Ca^{2+} -pump (also called a Ca^{2+} -ATPase), in its membrane (see [Figure 3-77](#)). Typically, the cytoplasmic Ca^{2+} concentration is restored to resting levels within 30 msec, allowing the myofibrils to relax. Thus, muscle contraction depends on two processes that consume enormous amounts of ATP: filament sliding, driven by the ATPase of the myosin motor domain, and Ca^{2+} pumping, driven by the Ca^{2+} -pump.

The Ca^{2+} dependence of vertebrate skeletal muscle contraction, and hence its dependence on motor commands transmitted via nerves, is due entirely to a set of specialized accessory proteins that are closely associated with the actin thin filaments. One of these accessory proteins is a muscle form of *tropomyosin*, an elongated molecule that binds along the groove of the actin helix. The other is *troponin*, a complex of three polypeptides, troponins T, I, and C (named for their tropomyosin-binding, inhibitory, and Ca^{2+} -binding activities, respectively). Troponin I binds to actin as well as to troponin T. In a resting muscle, the troponin I-T complex pulls the tropomyosin out of its normal binding groove into a position along the actin filament that interferes with the binding of myosin heads, thereby preventing any force-generating interaction. When the level of Ca^{2+} is raised, troponin C—which binds up to four molecules of Ca^{2+} —causes troponin I to release its hold on actin. This allows the tropomyosin molecules to slip back into their normal position so that the myosin heads can walk along the actin filaments ([Figure 16-74](#)). Troponin C is closely related to the ubiquitous Ca^{2+} -binding protein calmodulin (see [Figure 15-40](#)); it can be thought of as a specialized form of calmodulin that has acquired binding sites for troponin I and troponin T, thereby ensuring that the myofibril responds extremely rapidly to an increase in Ca^{2+} concentration. [↑ TOP](#)

Heart Muscle Is a Precisely Engineered Machine

The heart is the most heavily worked muscle in the body, contracting about 3 billion (3×10^9) times during the course of a human lifetime. This number is about the same as the average number of revolutions in the lifetime of an automobile's internal combustion engine. Several specific isoforms of cardiac muscle myosin and cardiac muscle actin are expressed in heart cells. Even subtle changes in contractile proteins expressed in the heart—changes that would not cause any noticeable consequences in other tissues—can cause serious heart disease ([Figure 16-75](#)).

Familial hypertrophic cardiomyopathy is a frequent cause of sudden death in young athletes. It is an inherited condition that affects about two out of every thousand people, and it is associated with heart enlargement, abnormally small

coronary vessels, and disturbances in heart rhythm (cardiac arrhythmias). Over 40 subtle point mutations in the genes encoding cardiac β myosin heavy chain (almost all causing changes in or near the motor domain), as well as about a dozen in other genes encoding contractile proteins, including myosin light chains, cardiac troponin, and tropomyosin, have been found that cause this condition. Minor missense mutations in the cardiac actin gene can cause another type of heart condition, called *dilated cardiomyopathy*, that also frequently results in early heart failure. The normal cardiac contractile apparatus seems to be such a highly tuned machine that a tiny abnormality anywhere in the works can be enough to gradually wear it down over years of repetitive motion. [↑ TOP](#)

Cilia and Flagella Are Motile Structures Built from Microtubules and Dyneins

Just as myofibrils are highly specialized and efficient motility machines built from actin and myosin filaments, cilia and flagella are highly specialized and efficient motility structures built from microtubules and dynein. Both cilia and flagella are hair-like cellular appendages that have a bundle of microtubules at their core. **Flagella** are found on sperm and many protozoa. By their undulating motion, they enable the cells to which they are attached to swim through liquid media ([Figure 16-76A](#)). **Cilia** tend to be shorter than flagella and are organized in a similar fashion, but they beat with a whip-like motion that resembles the breast stroke in swimming ([Figure 16-76B](#)). The cycles of adjacent cilia are almost but not quite in synchrony, creating the wave-like patterns that can be seen in fields of beating cilia under the microscope. Ciliary beating can either propel single cells through a fluid (as in the swimming of the protozoan *Paramecium*) or can move fluid over the surface of a group of cells in a tissue. In the human body, huge numbers of cilia ($10^9/\text{cm}^2$ or more) line our respiratory tract, sweeping layers of mucus, trapped particles of dust, and bacteria up to the mouth where they are swallowed and ultimately eliminated. Likewise, cilia along the oviduct help to sweep eggs toward the uterus.

The movement of a cilium or a flagellum is produced by the bending of its core, which is called the axoneme. The axoneme is composed of microtubules and their associated proteins, arranged in a distinctive and regular pattern. Nine special doublet microtubules (comprising one complete and one partial microtubule fused together so that they share a common tubule wall) are arranged in a ring around a pair of single microtubules ([Figure 16-77](#)). This characteristic arrangement is found in almost all forms of eucaryotic flagella and cilia from protozoans to humans. The microtubules extend continuously for the length of the axoneme, which can be 10–200 μm . At regular positions along the length of the microtubules, accessory proteins cross-link the microtubules together. Molecules of *ciliary dynein* form bridges between the neighboring doublet microtubules around the circumference of the axoneme ([Figure 16-78](#)). When the motor domain of this dynein is activated, the dynein

molecules attached to one microtubule doublet attempt to walk along the adjacent microtubule doublet, tending to force the adjacent doublets to slide relative to one another, much as actin thin filaments slide during muscle contraction. However, the presence of other links between the microtubule doublets prevents this sliding, and the dynein force is instead converted into a bending motion ([Figure 16-79](#)).

Bacteria also swim using cell surface structures called flagella, but these do not contain microtubules or dynein and do not wave or beat. Instead, *bacterial flagella* are long, rigid helical filaments, made up of repeating subunits of the protein flagellin. The flagella rotate like propellers, driven by a special rotary motor embedded in the bacterial cell wall (see [Figure 15-67](#)). The use of the same name to denote these two very different types of swimming apparatus is an unfortunate historical accident.

Structures called *basal bodies* firmly root eucaryotic cilia and flagella at the cell surface. The basal bodies have the same form as the centrioles that are found embedded at the center of animal centrosomes, with nine groups of fused triplet microtubules arranged in a cartwheel ([Figure 16-80](#)). Indeed, in some organisms, basal bodies and centrioles are functionally interconvertible: during each mitosis in the unicellular alga *Chlamydomonas*, for example, the flagella are resorbed, and the basal bodies move into the cell interior and become part of the spindle poles. New centrioles and basal bodies arise by a curious replication process, in which a smaller daughter is formed perpendicular to the original structure by a still mysterious mechanism (see [Figure 18-6](#)).

In humans, hereditary defects in ciliary dynein cause Kartagener's syndrome. The syndrome is characterized by male sterility due to immotile sperm, a high susceptibility to lung infections owing to the paralyzed cilia in the respiratory tract that fail to clear debris and bacteria, and defects in determination of the left-right axis of the body during early embryonic development (discussed in [Chapter 21](#)). [↑ TOP](#)

Summary

Motor proteins use the energy of ATP hydrolysis to move along microtubules or actin filaments. They mediate the sliding of filaments relative to one another and the transport of membrane-enclosed organelles along filament tracks. All known motor proteins that move on actin filaments are members of the myosin superfamily. The motor proteins that move on microtubules are members of either the kinesin superfamily or the dynein family. The myosin and kinesin superfamilies are diverse, with about 40 genes encoding each type of protein in humans. The only structural element shared among all members of each superfamily is the motor "head" domain. These heads can be attached to a wide variety of "tails," which attach to different types of cargo and enable the various family members to perform different functions in the cell. Although

myosin and kinesin walk along different tracks and use different mechanisms to produce force and movement by ATP hydrolysis, they share a common structural core, suggesting that they are derived from a common ancestor.

Two types of specialized motility structures in eucaryotic cells consist of highly ordered arrays of motor proteins that move on stabilized filament tracks. The myosin-actin system of the sarcomere powers the contraction of various types of muscle, including skeletal, smooth, and cardiac muscle. The dynein-microtubule system of the axoneme powers the beating of cilia and the undulations of flagella. [↑ TOP](#)

Figure 16-51. Myosin II. (A) A myosin II molecule is composed of two heavy chains (each about 2000 amino acids long (green) and four light chains (blue). The light chains are of two distinct types, and one copy of each type is present on each myosin head. Dimerization occurs when the two α helices of the heavy chains wrap around each other to form a coiled-coil, driven by the association of regularly spaced hydrophobic amino acids (see [Figure 3-11](#)). The coiled-coil arrangement makes an extended rod in solution, and this part of the molecule is called the tail. (B) The two globular heads and the tail can be clearly seen in electron micrographs of myosin molecules shadowed with platinum. (B, courtesy of David Shotton.)

Figure 16-54. Myosin superfamily tree. (A) A family tree for a few of the many known members of the myosin superfamily. The length of the lines separating individual family members indicates the amount of difference in the amino acid sequence of the motor domain. Groups of related myosins that share a similar structure are assigned a Roman numeral. The species of origin

of some of the myosins shown are indicated with colored dots. Some myosin types (such as I and II) have members in many eucaryotic species, ranging from animals to plants to parasitic protozoa; others are found only in particular groups of eucaryotes (XIV, for example, has been found so far only in parasitic protozoa such as *Toxoplasma* and *Plasmodium*). (B) Comparison of the domain structure of the heavy chains of some myosin types. All myosins share similar motor domains (shown in *dark green*), but their C-terminal tails (*light green*) and N-terminal extensions (*light blue*) are very diverse. On the right are depictions of the molecular structure for these family members. Many myosins form dimers, with two motor domains per molecule, but a few (such as I, IX, and XIV) seem to function as monomers, with just one motor domain. Myosin VI, despite its overall structural similarity to other family members, is unique in moving toward the minus end (instead of the plus end) of an actin filament. The small insertion within its motor head domain, not found in other myosins, is probably responsible for this change in direction.

Figure 16-55. Kinesin and kinesin-related proteins. (A) Structures of four kinesin superfamily members. As in the myosin superfamily, only the motor domains are conserved. Conventional kinesin has the motor domain at the N-terminus of the heavy chain. The middle domain forms a long coiled-coil, mediating dimerization. The C-terminal domain forms a tail that attaches to cargo, such as a membrane-enclosed organelle. KIFC2 is a member of a family of C-terminal kinesins that includes the *Drosophila* protein Ncd and the yeast protein KAR3. These kinesins generally travel in the opposite direction from the majority of kinesins, toward the minus end instead of the plus end of a microtubule. KIF2 has its motor domain located in the middle of the heavy chain. It is a member of a family of kinesins that have lost typical motor activity and instead bind to microtubule ends to increase dynamic instability of microtubules; they are therefore called catastrophins. KIF1B is a member of the unusual class of kinesins that seem to function as monomers and move membrane-enclosed organelles along microtubules. Not shown is the BimC family of kinesins, which form tetramers. (B) Freeze-etch electron micrograph of a kinesin molecule with the head domains on the left. (B, courtesy of John Heuser.)

ATTACHED At the start of the cycle shown in this figure, a myosin head lacking a bound nucleotide is locked tightly onto an actin filament in a *rigor* configuration (so named because it is responsible for *rigor mortis*, the rigidity of death). In an actively contracting muscle, this state is very short-lived, being rapidly terminated by the binding of a molecule of ATP.

RELEASED A molecule of ATP binds to the large cleft on the "back" of the head (that is, on the side furthest from the actin filament) and immediately causes a slight change in the conformation of the domains that make up the actin-binding site. This reduces the affinity of the head for actin and allows it to move along the filament. (The space drawn here between the head and actin emphasizes this change, although in reality the head probably remains very close to the actin.)

COCKED The cleft closes like a clam shell around the ATP molecule, triggering a large shape change that causes the head to be displaced along the filament by a distance of about 5 nm. Hydrolysis of ATP occurs, but the ADP and inorganic phosphate (P_i) produced remain tightly bound to the protein.

FORCE-GENERATING A weak binding of the myosin head to a new site on the actin filament causes release of the inorganic phosphate produced by ATP hydrolysis, concomitantly with the tight binding of the head to actin. This release triggers the power stroke—the force-generating change in shape during which the head regains its original conformation. In the course of the power stroke, the head loses its bound ADP, thereby returning to the start of a new cycle.

ATTACHED At the end of the cycle, the myosin head is again locked tightly to the actin filament in a *rigor* configuration. Note that the head has moved to a new position on the actin filament.

Figure 16-59. Comparison of the mechanochemical cycles of kinesin and myosin II. The shading in the two circles representing the hydrolysis cycle indicates the proportion of the cycle spent in attached and detached states for each motor protein. (A) Summary of the coupling between ATP hydrolysis and conformational changes for kinesin. At the start of the cycle, one of the two kinesin heads, the front or leading head (*dark green*) is bound to the microtubule, with the rear or trailing head (*light green*) detached. Binding of ATP to the front head causes the rear head to be thrown forward, past the binding site of the attached head, to another binding site further toward the plus end of the microtubule. Release of ADP from the second head (now in the front) and hydrolysis of ATP on the first head (now in the rear) brings the dimer back to the original state, but the two heads have switched their relative positions, and the motor protein has moved one step along the microtubule protofilament. In this cycle, each head spends about 50% of its time attached to the microtubule and 50% of its time detached. (B) Summary of the coupling between

ATP hydrolysis and conformational changes for myosin II. Myosin begins its cycle tightly bound to the actin filament, with no associated nucleotide, the so-called "rigor" state. ATP binding releases the head from the filament. ATP hydrolysis occurs while the myosin head is detached from the filament, causing the head to assume a cocked conformation, although both ADP and inorganic phosphate remain tightly bound to the head. When the head rebinds to the filament, the release of phosphate, followed by the release of ADP, trigger the power stroke that moves the filament relative to the motor protein. ATP binding releases the head to allow the cycle to begin again. In the myosin cycle, the head remains bound to the actin filament for only about 5% of the entire cycle time, allowing many myosins to work together to move a single actin filament.

Figure 16-60. Orientation of forward- and backward-walking kinesin superfamily proteins bound to microtubules. These images were generated by fitting the structures of the free motor-protein dimers (determined by x-ray crystallography) onto a lower resolution image of the dimers attached to microtubules (determined by cryoelectron microscopy). (A) Conventional kinesin has its motor domain at the protein's N-terminus and moves toward the plus end of the microtubule. When one head of the dimer is bound to the microtubule in a post-stroke state (with ATP in the nucleotide binding site), the second, unbound head is pointing toward the microtubule plus end, poised to take the next step. (B) Ncd, a minus-end-directed motor with the motor domain at the C-terminus, forms dimers with the opposite orientation. (From E. Sablin et al., *Nature* 395:813–816, 1998. © Macmillan Magazines Ltd.)

Figure 16-63. A model for the attachment of dynein to a membrane-enclosed organelle. Dynein requires the presence of a large number of accessory proteins to associate with membrane-enclosed organelles. Dynactin is a large complex (red) that includes components that bind weakly to microtubules, components that bind to dynein itself, and components that form a small actinlike filament made of the actin-related protein Arp1. It is thought that the Arp1 filament may mediate attachment of this large complex to membrane-enclosed organelles through a network of spectrin and ankyrin, similar to the membrane-associated cytoskeleton of the red blood cell (see [Figure 10-31](#)).

Figure 16-67. Light-chain phosphorylation and the regulation of the assembly of myosin II into thick filaments. (A) The controlled phosphorylation by the enzyme myosin light-chain kinase (MLCK) of one of the two light chains (the so-called regulatory light chain, shown in *light blue*) on nonmuscle myosin II in a test tube has at least two effects: it causes a change in the conformation of the myosin head, exposing its actin-binding site, and it releases the myosin tail from a "sticky patch" on the myosin head, thereby allowing the myosin molecules to assemble into short, bipolar, thick filaments. (B) Electron micrograph of negatively stained short filaments of myosin II that have been induced to assemble in a test tube by phosphorylation of their light chains. These myosin II filaments are much smaller than those found in skeletal muscle cells (see [Figure 16-52](#)). (B, courtesy of John Kendrick-Jones.)

Figure 16-72. Organization of accessory proteins in a sarcomere. Each giant titin molecule extends from the Z disc to the M line—a distance of over 1 μm . Part of each titin molecule is closely associated with a myosin thick filament (which switches polarity at the M line); the rest of the titin molecule is elastic and changes length as the sarcomere contracts and relaxes. Each nebulin molecule is exactly the length of a thin filament. The actin filaments are also coated with tropomyosin and troponin (not shown; see Figure 16-74) and are capped at both ends. Tropomodulin caps the minus end of the actin filaments, and CapZ anchors the plus end at the Z disc, which also contains α -actinin.

Figure 16-78. Ciliary dynein. Ciliary (axonemal) dynein is a large protein assembly (nearly 2 million daltons) composed of 9–12 polypeptide chains, the largest of which is the heavy chain of more than 500,000 daltons. (A) The heavy chains are believed to form the major portion of the globular head and stem domains, and many of the smaller chains are clustered around the base of the stem (see [Figure 16-56](#) for a view of the isolated molecule). The base of the molecule binds tightly to an A microtubule in an ATP-independent manner, while the large globular heads have an ATP-dependent binding site for a B microtubule (see [Figure 16-77](#)). When the heads hydrolyze their bound ATP, they move toward the minus end of the B microtubule, thereby producing a sliding force between the adjacent microtubule doublets in a cilium or flagellum. The three-headed form of ciliary dynein, formed from three heavy chains, is illustrated here. (B) Freeze-etch electron micrograph of a cilium showing the dynein arms projecting at regular intervals from the doublet microtubules; only the A microtubule is shown. (B, courtesy of John Heuser.)

The Cytoskeleton and Cell Behavior

A central challenge in all areas of cell biology is to understand how the functions of many individual molecular components combine to produce complex cell behaviors. Thus far in this chapter, we have seen how various basic cytoskeletal mechanisms, such as muscle contraction, can be understood in terms of the activities of just a few types of molecules. In this final section, we examine more complex cell behaviors and consider how they are built up from these basic cytoskeletal mechanisms.

The cell behaviors that we describe all rely on coordinated deployment of the same components and processes that we have explored in the first three sections of the chapter: the dynamic assembly and disassembly of cytoskeletal polymers, the regulation and modification of their structure by polymer-associated proteins, and the actions of motor proteins moving along the polymers. How are all these activities coordinated to define a cell's shape, to enable it to crawl, or to divide it neatly into two at mitosis? These problems of cytoskeletal coordination will challenge scientists for many years to come. We shall focus on the control of cell shape and locomotion here, leaving the role of the cytoskeleton in cell division for discussion in [Chapter 18](#).

Mechanisms of Cell Polarization Can Be Readily Analyzed in Yeast Cells

Compared with most animal cells, the budding yeast *Saccharomyces cerevisiae* has a very simple structure. The most notable feature is the marked asymmetry of the yeast cell, evident in the asymmetrical way it divides by budding to create a small daughter cell and a large mother cell. This asymmetry derives from the polar orientation of its actin cytoskeleton. Because genetic analysis in yeast is relatively easy, it has been possible to use genetic screens to identify many of the molecules involved in generating and maintaining this cell polarity. As in other fields where budding yeast has proved its utility as a model organism for cell biologists, most of these molecules have turned out to have homologs with similar functions in more complex cells.

Budding yeast cells are unusual among eucaryotes in having very few cytoplasmic microtubules, so that most aspects of its polarity depend on actin. There are two types of actin filament assemblies in these cells: actin cables (long bundles of actin filaments) and actin patches (small assemblies of filaments associated with the cell cortex, probably marking sites of endocytosis and exocytosis). Proliferating budding yeast cells must be highly polarized to allow the mother cell to grow a bud from a single site on the cell surface. In this process, the actin patches are highly concentrated at the growing tip of the bud, with the actin cables aligned and pointing toward them. This actin organization presumably directs the secretion of new cell wall material to the site of budding ([Figure 16-81](#)).

On starvation, yeasts, like many other unicellular organisms, sporulate. But sporulation can occur only in diploid budding yeast cells, whereas budding yeasts mainly proliferate as haploid cells. A starving haploid individual must therefore locate a partner of the opposite mating type, woo it, and mate with it before sporulating. Yeast cells are unable to swim and, instead, reach their mates by polarized growth. The haploid form of budding yeast comes in two mating types, a and α , which secrete mating factors known as a -factor and α -factor, respectively. These secreted signal molecules act by binding to cell-surface receptors that belong to the G-protein-linked receptor superfamily discussed in [Chapter 15](#). One consequence of the binding of α -factor to its receptor is to cause the recipient cell to become polarized, adopting a shape known as a "shmoo" ([Figure 16-82](#)). In the presence of an α -factor gradient, the a -cell shmoo tip is directed toward the highest concentration of the signal molecule, which under normal circumstances would direct it toward an amorous α cell located nearby.

This polarized cell growth requires alignment of the actin cytoskeleton in response to the mating factor signal. When the signal binds to its receptor, the receptor activates Cdc42, the Rho-family GTPase that is also responsible for some types of actin rearrangements in animal cells (see [Figure 16-50D](#)). The signals that the actin cytoskeleton receives from the outside world are then relayed to the microtubule cytoskeleton, causing polarized growth. In addition, the microtubule-organizing center (which in yeast is embedded in the nuclear membrane and is called the *spindle pole body*) rotates to the side of the nucleus that is closest to the shmoo tip, so that the nucleus becomes oriented along an axis that will guide it to meet and fuse with the nucleus of its mating partner. Extensive genetic studies have identified most of the genes involved in receiving and transducing this spatial signal. As might be expected, many of the proteins that they encode are involved in regulating actin filament and microtubule rearrangements ([Figure 16-83](#)).

Haploid budding yeast cells use this same polarization machinery during vegetative growth. To form the bud that will grow out to become a daughter cell, the yeast must direct new plasma membrane and cell wall material primarily to a single site. As with shmoo formation, this requires an initial

[Figure 16-100. The](#)

[complex architecture of a...](#)

cytoskeletal polarity, with most actin patches in the growing bud and actin cables oriented along the bud axis. In haploid cells, a new bud site is always constructed immediately adjacent to the previous bud site. In this case, the spatial cues that set up cytoskeletal polarity are intrinsic to the cell, left behind from previous rounds of cell division. Cdc42 is once again involved in transducing the signal from the destined bud site to the cytoskeleton, and most of the proteins involved in the upstream and downstream pathways have been identified through genetic experiments. Subsequent to their identification in yeast, many of these proteins have been found to have homologs in other organisms, where they are often likewise involved in the establishment of cell polarity. [↑ TOP](#)

Specific RNA Molecules Are Localized by the Cytoskeleton

The cytoskeleton is used to position RNA molecules as well as proteins in cells. The yeast mother and daughter cells retain distinct identities, as revealed by major differences in their subsequent ability to undergo mating-type switching (discussed in [Chapter 7](#)) and in the choice of their next bud site.

Many of these differences are caused by a gene regulatory protein called *Ash1*. Both *ash1* mRNA and protein are localized exclusively to the growing bud and therefore end up only in the daughter cell. One of the two type V myosins found in yeast, MyoV, is required for this asymmetric distribution of *ash1* mRNA. A genetic screen for other mutations that disrupt the mother/daughter difference has revealed that at least six other gene products that are associated with the cytoskeleton are required for normal polarity; these include tropomyosin, profilin, and actin itself, as well as a complex of two proteins that form a direct link between a specific sequence in the *ash1* mRNA and the myosin V protein ([Figure 16-84](#)).

This type of selective positioning of RNA represents yet another way in which the cytoskeleton is involved in cell polarity. For example, in the developing *Drosophila* embryo (discussed in [Chapter 21](#)), a group of mRNAs that encode genes necessary for proper development of the posterior region of the embryo are localized posteriorly by their association with actin filaments, but only after they are transported there by motor proteins moving along oriented microtubules. Identifying the molecules and organizational principles that determine cell polarity in these more complex systems is an active area of research. [↑ TOP](#)

Many Cells Can Crawl Across A Solid Substratum

Many cells move by crawling over surfaces rather than by using cilia or flagella to swim. Predatory amoebae crawl continuously in search of food, and they can easily be observed to attack and devour smaller ciliates and flagellates in a drop of pond water. In animals, almost all cell locomotion occurs by crawling, with the notable exception of swimming sperm. During embryogenesis, the structure of an animal is created by the migrations of

individual cells to specific target locations and by the coordinated movements of whole epithelial sheets. In vertebrates, *neural crest cells* are remarkable for their long-distance migrations from their site of origin in the neural tube to a variety of sites throughout the embryo. These cells have diverse fates, becoming skin pigment cells, sensory and sympathetic neurons and glia, and various structures of the face. Long-distance crawling is fundamental to the construction of the entire nervous system: it is in this way that the actin-rich growth cones at the advancing tips of developing axons travel to their eventual synaptic targets, guided by combinations of soluble signals and signals bound to cell surfaces and extracellular matrix along the way.

The adult animal is also seething with crawling cells. Macrophages and neutrophils crawl to sites of infection and engulf foreign invaders as a critical part of the innate immune response. Osteoclasts tunnel into bone, forming channels that are filled in by the osteoblasts that follow after them, in a continuous process of bone remodeling and renewal. Similarly, fibroblasts can migrate through connective tissues, remodeling them where necessary and helping to rebuild damaged structures at sites of injury. In an ordered procession, the cells in the epithelial lining of the intestine travel up the sides of the intestinal villi, replacing absorptive cells lost at the tip of the villus. Cell crawling also has a role in many cancers, when cells in a primary tumor invade neighboring tissues and crawl into blood vessels or lymph vessels and are thereby carried to other sites in the body to form metastases.

Cell crawling is a highly complex integrated process, dependent on the actin-rich cortex beneath the plasma membrane. Three distinct activities are involved: *protrusion*, in which actin-rich structures are pushed out at the front of the cell; *attachment*, in which the actin cytoskeleton connects across the plasma membrane to the substratum; and *traction*, in which the bulk of the trailing cytoplasm is drawn forward (Figure 16-85). In some crawling cells, such as keratocytes from the fish epidermis, these activities are closely coordinated, and the cells seem to glide forward smoothly without changing shape. In other cells, such as fibroblasts, these activities are more independent, and the locomotion is jerky and irregular. [↑ TOP](#)

Plasma Membrane Protrusion Is Driven by Actin Polymerization

The first step in locomotion, protrusion of a leading edge, seems to rely primarily on forces generated by actin polymerization pushing the plasma membrane outward. Different cell types generate different types of protrusive structures, including filopodia (also known as microspikes), lamellipodia, and pseudopodia. All are filled with a dense core of filamentous actin, which excludes membrane-enclosed organelles. The three structures differ primarily in the way in which the actin is organized—in one, two, or three dimensions, respectively—and we have already discussed how this results from the presence of different actin-associated proteins.

Filopodia, formed by migrating growth cones and some types of fibroblasts, are essentially one-dimensional. They contain a core of long, bundled actin filaments, which are reminiscent of those in microvilli but longer and thinner, as well as more dynamic. **Lamellipodia**, formed by epithelial cells and fibroblasts, as well as by some neurons, are two-dimensional, sheet-like structures. They contain an orthogonally cross-linked mesh of actin filaments, most of which lie in a plane parallel to the solid substratum. **Pseudopodia**, formed by amoebae and neutrophils, are stubby three-dimensional projections filled with an actin-filament gel. Perhaps because their two-dimensional geometry is most convenient for examination with the light microscope, we know more about the dynamic organization and protrusion mechanism of lamellipodia than we do for either filopodia or pseudopodia.

Lamellipodia contain all of the machinery that is required for cell motility. They have been especially well studied in the epithelial cells of the epidermis of fish and frogs, which are known as "keratocytes" because of their abundant keratin filaments. These cells normally cover the animal by forming an epithelial sheet, and they are specialized to close wounds very rapidly, moving at rates up to 30 $\mu\text{m}/\text{min}$. When cultured as individual cells, keratocytes assume a distinctive shape with a very large lamellipodium and a small, trailing cell body that is not attached to the substratum (Figure 16-86). Fragments of this lamellipodium can be sliced off with a micropipette. Although the fragments generally lack microtubules and membrane-enclosed organelles, they continue to crawl normally, looking like tiny keratocytes (Figure 16-87).

The dynamic behavior of actin filaments can be studied in keratocyte lamellipodia by marking a small patch of actin and examining its fate. This reveals that, while the lamellipodia crawl forward, the actin filaments remain stationary with respect to the substrate. The actin filaments in the meshwork are mostly oriented with their plus ends facing forward. The minus ends are frequently attached to the sides of other actin filaments by ARP complexes (see Figure 16-28), helping to form the two-dimensional web (Figure 16-88). The web as a whole seems to be undergoing treadmilling, assembling at the front and dis-assembling at the back, reminiscent of the treadmilling that occurs in individual actin filaments and microtubules discussed previously (see Figure 16-9).

Maintenance of unidirectional motion by lamellipodia is thought to require the cooperation and mechanical integration of several factors. Filament nucleation is localized at the leading edge, with new actin filament growth occurring primarily in that location to push the plasma membrane forward. Most filament depolymerization occurs at sites located well behind the leading edge. Because *cofilin* (see Figure 16-34) binds cooperatively and preferentially to actin filaments containing ADP-actin (the D form), the new T-form filaments generated at the leading edge should be resistant to depolymerization by cofilin (Figure 16-89). As the filaments age and ATP hydrolysis proceeds, cofilin can

efficiently disassemble the older filaments. Thus, the delayed ATP hydrolysis by filamentous actin is thought to provide the basis for a mechanism that maintains an efficient, unidirectional treadmilling process in the lamellipodium (Figure 16-90). Finally, bipolar myosin II filaments seem to associate with the actin filaments in the web and pull them into a new orientation—from nearly perpendicular to the leading edge to an orientation almost parallel to the leading edge. This contraction prevents protrusion and it pinches in the sides of the locomoting lamellipodium, helping to gather in the sides of the cell as it moves forward. [↑ TOP](#)

Cell Adhesion and Traction Allow Cells to Pull Themselves Forward

Current evidence suggests that lamellipodia of all cells share this basic, simple type of dynamic organization, but the interactions between the cell and its physical environment usually make the situation considerably more complex than for fish keratocytes crawling on a culture dish. Particularly important in locomotion is the intimate crosstalk between the cytoskeleton and cell adhesion. Although some degree of adhesion to the substratum is necessary for any form of cell crawling, adhesion and locomotion rate seem generally to be inversely related, with highly adhesive cells moving more slowly than weakly adhesive ones. Keratocytes are so weakly adhesive to the substratum that the force of actin polymerization can push the leading edge forward very rapidly. In contrast, when neurons from the sea slug *Aplysia* are cultured on a sticky substratum, they form large lamellipodia that become stuck too tightly to move forward. In these lamellipodia, the same cycle of localized nucleation of new actin filaments, depolymerization of old filaments, and myosin-dependent contraction continues to operate. But because the leading edge is prevented physically from moving forward, the entire actin mesh moves backward toward the cell body instead (Figure 16-91). The adhesion of most cells lies somewhere between these two extremes, and most lamellipodia exhibit some combination of forward actin filament protrusion (like keratocytes) and rearward actin flux (like the *Aplysia* neurons).

As a lamellipodium, filopodium, or pseudopodium extends forward over a substratum, it can form new attachment sites. These sites can be seen by *interference reflection microscopy*, as sites where the cell plasma membrane is extremely close to the substratum. In crawling cells, the individual attachment sites, which contain much of the same molecular machinery found in focal contacts (see Figure 16-49), generally form at the cell front and remain stationary as the cell moves forward over them, persisting until the rear of the cell catches up with them. When an individual lamellipodium fails to adhere to the substratum, it is usually lifted up onto the dorsal surface of the cell and rapidly carried backward as a "ruffle" (Figure 16-92).

The attachment sites established at the leading edge serve as anchorage points, which allow the cell to generate traction on the substratum and pull its body

forward. Traction forces seem to be generated by myosin motor proteins, especially myosin II. In many locomoting cells, myosin II is highly concentrated at the posterior of the cell ([Figure 16-93](#)). *Dictyostelium* amoebae that are deficient in myosin II are able to protrude pseudopodia at normal speeds, but the translocation of their cell body is much slower than that of wild-type amoebae, indicating the importance of myosin II contraction in this part of the cell locomotion cycle. It is not clear how the activity of myosin II pulls the cell body forward. One might imagine that contractile bundles of actin and myosin linking the back of the cell to the front would be responsible; but the observed distribution of myosin II, in some cells at least, suggests a somewhat different strategy, which is depicted in [Figure 16-85](#). Contraction of the actin-rich cortex at the rear of the cell may also selectively weaken the older adhesive interactions that tend to hold the cell back. In addition, myosin II may transport cell body components forward over a polarized array of actin filaments.

The traction forces generated by locomoting cells exert a significant pull on the substratum ([Figure 16-94](#)). In a living animal, most crawling cells move across a semiflexible substratum made of extracellular matrix, which can be deformed and rearranged by these cell forces. In culture, movement of fibroblasts through a gel of collagen fibrils aligns the collagen, generating an organized extracellular matrix that in turn affects the shape and direction of locomotion of the fibroblasts within it ([Figure 16-95](#)). This two-way mechanical interaction between cells and their physical environment is thought to be a major way that vertebrate tissues organize themselves. [↑ TOP](#)

External Signals Can Dictate the Direction of Cell Migration

Cell locomotion requires an initial polarization of the cell to set it off in a particular direction. Carefully controlled cell polarization processes are also required for oriented cell divisions in tissues and for formation of a coherent, organized multicellular structure. The molecular mechanisms that generate cell polarity are only beginning to be understood for vertebrates. Most of what we know so far about the topic has been learned through genetic studies in yeasts, flies, and worms. In all known cases, however, the cytoskeleton has a central role, and many of the molecular components have been evolutionarily conserved.

Polarized cell movement is of little use unless it is responsive to cues in the environment, and these can be both chemical and physical. *Chemotaxis* is defined as cell movement in a direction controlled by a gradient of a diffusible chemical. One well-studied example is the chemotactic movement of a class of white blood cells, called *neutrophils*, toward a source of bacterial infection. Receptor proteins on the surface of neutrophils enable them to detect the very low concentrations of the *N*-formylated peptides that are derived from bacterial proteins (only procaryotes begin protein synthesis with *N*-formylmethionine). Using these receptors, neutrophils are guided to bacterial targets by their

ability to detect a difference of only 1% in the concentration of these diffusible peptides on one side of the cell versus the other (Figure 16-96). Both in this case and in the similar chemotaxis of *Dictyostelium* amoebae toward a source of cyclic AMP, a local polymerization of actin near the receptors is stimulated when the receptors bind their ligands. This actin polymerization response depends on the monomeric Rho-family GTPases discussed earlier. As in the shmooing yeast (see Figure 16-83), the responding cell extends a protrusion toward the signal. The preferential localization of protrusive activity toward one side of the cell indirectly causes reorientation of the traction-generating machinery, and the cell body then follows its "nose" and moves toward the attractive signal.

The direction of cell migration can also be influenced by nondiffusible chemical cues attached to the extracellular matrix or to the surface of cells. Receptor activation by these signals can cause increased cell adhesion, in addition to directed actin polymerization. Most long-distance cell migrations in animals, including neural-crest-cell migration and the travels of neuronal growth cones, depend on a combination of diffusible and non-diffusible signals to steer the locomoting cells or growth cones to their proper destinations (see Figure 21-98).

To help organize persistent movement in a particular direction cells use their microtubules. In many locomoting cells, the position of the centrosome is influenced by the location of protrusive actin polymerization, being found on the forward side of the nucleus. The mechanism of centrosome reorientation is not clear. It is thought that the activation of receptors on one edge of a cell might not only stimulate actin polymerization there (and therefore local protrusion) but also locally activate dynein-like motor proteins that move the centrosome by pulling on its microtubules. The centrosome nucleates a large number of dynamic microtubules, and its repositioning means that many of these have their plus ends extending from the centrosome into the protrusive region of the cell. The dynamic microtubule plus ends may indirectly modulate local adhesion and also activate the Rac GTPase to further increase actin polymerization in the protrusive region. The increased concentration of microtubules would thereby encourage further protrusion, creating a positive feedback loop that enables protrusive motility to persist in the same direction for a prolonged period. Regardless of the exact mechanism, the orientation of the centrosome seems to reinforce the polarity information that the actin cytoskeleton receives from the outside world, allowing a sensitive response to weak signals.

A similar cooperative feedback loop seems to operate in other instances of cell polarization. A particularly interesting example is the killing of specific target cells by cytotoxic T lymphocytes. These cells kill other cells that carry foreign antigens on their surface and are a critical component of the vertebrate's adaptive immune response to infection. When the receptors on the surface of the T cell recognize antigen on the surface of the target cell, Rho-family GTPases are activated and cause actin polymerization under the zone of

contact between the two cells, creating a specialized region of the cortex. This specialized site causes the centrosome to reorient, moving with its microtubules to the zone of T-cell-target contact ([Figure 16-97](#)). The microtubules, in turn, position the Golgi apparatus right under the contact zone, focusing the killing machinery onto the target cell. The mechanism of killing is discussed in [Chapter 24](#). [↑ TOP](#)

The Complex Morphological Specialization of Neurons Depends on The Cytoskeleton

Many of the most striking differences between eucaryotic and prokaryotic cells are consequences of the eucaryotic cytoskeleton. The regulated, directed transport of intracellular components by motor proteins enables the eucaryotic cell to enlarge beyond the limits set by the speed of diffusion, which restrict procaryotic cell growth. At the same time, the cytoskeleton provides the framework for the elaborate architectures so characteristic of eucaryotic cells ([Figure 1-27](#); [Panel 16-1](#)). No cell exemplifies these two features of size and architectural complexity better than a neuron.

Neurons begin life in the embryo as unremarkable cells, which use actin-based motility to migrate to specific locations. Once there, however, they send out a series of long specialized processes that will either receive electrical signals (*dendrites*) or transmit these electrical signals to their target cells (*axons*). Both types of processes (collectively called *neurites*) are filled with bundles of microtubules, which are critical to both their structure and their function.

In axons, all the microtubules are oriented in the same direction, with their minus end pointing back toward the cell body and their plus end pointing forward toward the axon terminals ([Figure 16-98](#)). The microtubules do not reach from the cell body all the way to the axon terminals; each is typically only a few micrometers in length, but large numbers are staggered in an overlapping array. This set of perfectly aligned microtubule tracks acts as a highway to transport many specific proteins and protein-containing vesicles. These are needed at the axon terminals, where synapses must be constructed and maintained, but they are made only in the cell body and dendrites where the cell keeps all its ribosomes. The longest axon in the human body reaches from the base of the spinal cord to the tip of the big toe, being up to a meter in length. Mitochondria, large numbers of specific proteins in transport vesicles, and synaptic vesicle precursors make the long journey in the forward (anterograde) direction. They are carried there by plus-end-directed kinesin-family motor proteins that can move them a meter in about a day, which is a great improvement over diffusion, which would take approximately 8 years to move a mitochondrion this distance. Many members of the kinesin superfamily contribute to this *anterograde axonal transport*, most carrying specific subsets of membrane-enclosed organelles along the microtubules. The great diversity of the kinesin family motor proteins used in axonal transport suggests that they are involved in specific targeting, as well as in movement. At the same time,

old components from the axon terminals are carried back to the cell body for degradation and recycling; this *retrograde axonal transport* occurs along the same set of oriented microtubules, and it relies on cytoplasmic dynein, which is a minus-end-directed motor protein.

Axonal structure depends on these microtubules, as well as on the contributions of the other two major cytoskeletal systems—actin filaments and intermediate filaments. Actin filaments line the cortex of the axon, just beneath the plasma membrane, and actin-based motor proteins such as myosin V are also abundant in the axon, perhaps to help move materials, although their exact function is still unclear. Neurofilaments, the specialized intermediate filaments of nerve cells, provide the most important structural support in the axon. A disruption in neurofilament structure, or in the cross-linking proteins that attach the neurofilaments to the microtubules and actin filaments distributed along the axon, can result in axonal disorganization and eventually axonal degeneration.

The construction of the elaborate branching architecture of the neuron during development depends on actin-based motility. As mentioned earlier, the tips of growing axons and dendrites extend by means of a *growth cone*, a specialized motile structure rich in actin ([Figure 16-99](#)). Most neuronal growth cones produce filopodia, and some make lamellipodia as well. The protrusion and stabilization of growth-cone filopodia are exquisitely sensitive to environmental cues. Some cells secrete soluble proteins such as netrin to attract or repel growth cones. In addition, there are fixed guidance markers along the way, attached to the extracellular matrix or to the surfaces of cells. When a filopodium encounters such a "guidepost" in its exploration, it quickly forms adhesive contacts. It is thought that a myosin-dependent collapse of the actin meshwork in the unstabilized part of the growth cone then causes the developing axon to turn toward the guidepost. Other extracellular directional signals act as repellents and cause growth cone collapse at the site of signal action. A complex combination of positive and negative signals, both soluble and insoluble, accurately guide the growth cone to its final destination (discussed in [Chapter 21](#)).

Microtubules reinforce the directional decisions made by the actin-rich protrusive structures at the leading edge of the growth cone. Microtubules from the axonal parallel array just behind the growth cone are constantly growing into the growth cone and shrinking back by dynamic instability. Adhesive guidance signals are somehow relayed to the dynamic microtubule ends, so that microtubules growing in the correct direction are stabilized against disassembly. In this way, a microtubule-rich axon is left behind, marking the path that the growth cone has traveled.

Dendrites are generally much shorter projections than axons, and they function to receive signals rather than to send them. The microtubules in dendrites all lie parallel to one another but their polarities are mixed, with some pointing their plus ends toward the dendrite tip, while others point back toward the cell

body. Nevertheless, dendrites also form as the result of growth-cone activity (see [Figure 21-97](#)). Travelling along their complex paths, the growth cones at the tips of both axons and dendrites create the intricate and highly individual morphology of each mature neuronal cell ([Figure 16-100](#)). In this way, the cytoskeleton provides the engine for construction of the entire nervous system, as well as the supporting structures that strengthen, stabilize, and maintain its parts.

Summary

Whole-cell movements and the large-scale shaping and structuring of cells require the coordinated activities of all three basic filament systems along with a large variety of cytoskeletal accessory proteins, including motor proteins. Cell crawling—a widespread behavior important in embryonic development and also in wound healing, tissue maintenance, and immune system function in the adult animal—is a prime example of such complex coordinated cytoskeletal action. For a cell to crawl, it must generate and maintain an overall structural polarity, which is influenced by external cues. Interactions between the microtubule and actin cytoskeletons reinforce this polarity. In addition, the cell must coordinate protrusion at the leading edge (by assembly of new actin filaments), adhesion of the newly protruded part of the cell to the substratum, traction via molecular motors to bring the cell body forward, and disassembly of old cell-substratum contacts.

Nowhere is the elaborate potential of eucaryotic cell morphology better illustrated than in the neuron. Neurons may be many millimeters long, with exceedingly complex dendrites and axons. The elaboration and maintenance of these beautiful and astonishingly complex cells requires the coordinated assembly of microtubules, neurofilaments, and actin filaments, as well as the actions of dozens of highly specialized molecular motors to transport subcellular components to their required destinations.

At the other end of the complexity spectrum, the budding yeast *Saccharomyces cerevisiae* uses its cytoskeletal plasticity to change shape during vegetative growth and during mating. Through genetic analyses, many of the molecular components that are required for these processes were first identified in yeast. Quite surprisingly, it has turned out that most of the same proteins also mediate the polarity and movements of animal cells, including those of humans. [↑ TOP](#)

Figure 16-81. Polarity of actin patches and cables throughout the yeast cell cycle. Filamentous actin structures in the yeast cell, labeled here with fluorescent phalloidin, include actin patches (round bright spots) and actin cables (extended lines). (A) In a mother cell, before the formation of the bud, most of the patches are clustered at one end. The cables are lined up and point toward the cluster of patches, which is the site where the bud will emerge. (B) As the small bud grows, most patches remain within it. Cables in the mother cell continue to point toward this site of new cell wall growth. (C) Patches are almost uniformly distributed over the surface of a full-sized bud. Cables in the mother cell remain polarized. (D) Immediately after cell division, mother and daughter cells form new patches, which are concentrated near the division site, although both cells have randomly oriented cables. (From T.S. Karpova et al., *J. Cell Biol.* 142:1501–1517, 1998. © The Rockefeller University Press.)

Figure 16-83. The signaling pathway in the yeast mating factor response. The extracellular mating factor binds to a G-protein-linked receptor in the plasma membrane. Activation of the receptor triggers dissociation of the GTP-bound $G\alpha$ subunit from a heterotrimeric G-protein (discussed in [Chapter 15](#)). This in turn activates the Rho family GTP-binding protein, Cdc42, the yeast homolog of the mammalian small GTPase whose activation triggers the formation of filopodia (see [Figure 16-50D](#)). As in mammalian cells, Cdc42 activates a protein (Bee1, the homolog of WASp) that activates the ARP complex, leading to local actin nucleation at the site of mating factor binding. The local actin nucleation and filament growth lead to polarized growth and acquisition of a shmoo shape. In addition, receptor activation triggers other responses through a MAP kinase cascade (discussed in [Chapter 15](#)), preparing the haploid cell for mating (not shown).

***Molecular Biology of the Cell* → IV. Internal Organization of the Cell → 16. The Cytoskeleton → The Cytoskeleton and Cell Behavior**

Figure 16-85. A model of how forces generated in the actin-rich cortex move a cell forward. The actin-polymerization-dependent protrusion and firm attachment of a lamellipodium at the leading edge of the cell moves the edge forward (*green arrows at front*) and stretches the actin cortex. Contraction at the rear of the cell propels the body of the cell forward (*green arrow at back*) to relax some of the tension (traction). New focal contacts are made at the front, and old ones are disassembled at the back as the cell crawls forward. The same cycle can be repeated, moving the cell forward in a stepwise fashion. Alternatively, all steps can be tightly coordinated, moving the cell forward smoothly. The newly polymerized cortical actin is shown in *red*.

Figure 16-86. Migratory keratocytes from a fish epidermis. (A) Light micrographs of a keratocyte in culture, taken about 15 sec apart. This cell is moving at about 15 $\mu\text{m}/\text{sec}$. (B) Keratocyte seen by scanning electron microscopy, showing its broad, flat lamellipodium and small cell body, including the nucleus, carried up above the substratum at the rear. (C) Distribution of cytoskeletal filaments in this cell. Actin filaments (*red*) fill the large lamellipodium and are responsible for the cell's rapid movement. Microtubules (*green*) and intermediate filaments (*blue*) are restricted to the regions close to the nucleus. (A and B, courtesy of Juliet Lee.)

Figure 16-87. Behavior of lamellipodial fragments. Fragments of the large lamellipodium of a keratocyte can be separated from the main cell, either by surgery with a micropipette or by treating the cell with certain drugs. (A) Many of these fragments continue to move rapidly, with the same overall cytoskeletal organization as the intact keratocytes. Actin (*blue*) forms a protrusive meshwork at the front of the fragment. Myosin II (*pink*) is gathered into a band at the rear. This cell fragment was moving toward the top of the photo at the time that it was fixed and stained. (B) Some of the fragments stop moving and assume a symmetric, circular shape. Actin (*blue*) is distributed uniformly around the circumference, and myosin (*pink*) is found in spots throughout the cytoplasm. These circular fragments are trying to protrude uniformly in all directions and are therefore paralyzed. Only by coordinating protrusion at the front with contraction at the rear can steady movement be maintained. (From A. Verkovsky et al., *Curr. Biol.* 9:11–20, 1999. © Elsevier.)

Molecular Biology of the Cell → IV. Internal Organization of the Cell → 16. The Cytoskeleton → The Cytoskeleton and Cell Behavior

Figure 16-88. Actin filament nucleation and web formation by the ARP complex in lamellipodia. (A) A keratocyte with actin filaments labeled in *red* by fluorescent phalloidin, and the ARP complex labeled in *green* with an antibody raised against one of its component proteins. The regions where the two overlap appear *yellow*. The ARP complex is highly concentrated near the front of the lamellipodium, where actin nucleation is most active. (B) Electron micrograph of a platinum-shadowed replica of the leading edge of a keratocyte, showing the dense actin filament meshwork. The labels denote areas enlarged in C. (C) Closeup views of the marked regions of the actin web

at the leading edge shown in B. Numerous branched filaments can be seen, with the characteristic 70° angle formed when the ARP complex nucleates a new actin filament off the side of a preexisting filament (see [Figure 16-29](#)). Figure 16-90. A model for protrusion of the actin meshwork at the leading edge.

Two time points during advance of the lamellipodium are illustrated, with newly assembled structures at the later time point shown in a lighter color. Nucleation is mediated by the ARP complex at the front. Newly nucleated actin filaments are attached to the sides of preexisting filaments, primarily at a 70° angle. Filaments elongate, pushing the plasma membrane forward because of some sort of anchorage of the array behind. At a steady rate, actin filament plus ends become capped. After newly polymerized actin subunits hydrolyze their bound ATP in the filament lattice, the filaments become susceptible to depolymerization by cofilin. This cycle causes a spatial separation between net filament assembly at the front and net filament disassembly at the rear, so that the actin filament network as a whole can move forward, even though the individual filaments within it remain stationary with respect to the substratum.

Figure 16-91. Rearward movement of the actin network in a growth-cone lamellipodium. (A) A growth cone from a neuron of the sea slug *Aplysia* is cultured on a highly adhesive substratum and viewed by differential-interference-contrast microscopy. Microtubules and membrane-enclosed organelles are confined to the bright, rear area of the growth cone (to the *left*), while a meshwork of actin filaments fills the lamellipodium (on the *right*). (B) After brief treatment with the drug cytochalasin, which caps the plus ends of actin filaments (see Table 16-2), the actin meshwork has detached from the front edge of the lamellipodium and has been pulled backward. (C) At the time point shown in B, the cell was fixed and labeled with fluorescent phalloidin to show the distribution of the actin filaments. Some actin filaments persist at the leading edge, but the region behind the leading edge is devoid of filaments. Note the sharp boundary of the rearward-moving actin meshwork. (D) The complex cyclic structure of cytochalasin B. (A, B, and C courtesy of Paul Forscher.)

Figure 16-96. Neutrophil polarization and chemotaxis. The pipette tip at the right is leaking a small amount of the peptide formyl-Met-Leu-Phe. Only bacterial proteins have formylated methionine residues, so the human neutrophil recognizes this peptide as the product of a foreign invader (discussed in [Chapter 25](#)). The neutrophil quickly extends a new lamellipodium toward the source of the chemoattractant peptide (*top*). It then extends this lamellipodium and polarizes its cytoskeleton so that contractile myosin II is located primarily at the rear, opposite the position of the lamellipodium (*middle*). Finally, the cell crawls toward the source of this peptide (*bottom*). If a real bacterium were the source of the peptide, rather than an investigator's pipette, the neutrophil would engulf the bacterium and destroy it. (From O.D. Weiner et al., *Nature Cell Biol.* 1:75–81, 1999. © Macmillan Magazines Ltd.)

Figure 16-97. The polarization of a cytotoxic T cell after target-cell recognition. (A) Changes in the cytoskeleton of a cytotoxic T cell after it has made contact with a target cell. The initial recognition event results in signals that cause actin polymerization in both cells at the site of contact. In the T cell, interactions between the actin-rich contact zone and microtubules emanating from the centrosome result in reorientation of the centrosome, so that the associated Golgi apparatus is directly apposed to the target cell. (B) Immuno-fluorescence micrograph in which both the T cell (*top*) and its target cell (*bottom*) have been stained with an antibody against microtubules. The centrosome and the microtubules radiating from it in the T cell are oriented toward the point of cell-cell contact. In contrast, the microtubule array in the target cell is not polarized. (B, from B. Geiger, D. Rosen and G. Berke, *J. Cell Biol.* 95:137–143, 1982. © The Rockefeller University Press.)

Figure 16-98. Microtubule organization in fibroblasts and neurons. (A) In a fibroblast, microtubules emanate outward from the centrosome in the middle of the cell. Vesicles with plus-end-directed kinesin attached move outward, and vesicles with minus-end-directed dynein attached move inward. (B) In a neuron, microtubule organization is more complex. In the axon, all microtubules share the same polarity, with the plus ends pointing outward toward the axon terminus. No one microtubule stretches the entire length of the axon; instead, short overlapping segments of parallel microtubules make the tracks for fast axonal transport. In dendrites, the microtubules are of mixed polarity, with some plus ends pointing outward and some pointing inward.

17. The Cell Cycle and Programmed Cell Death

"Where a cell arises, there must be a previous cell, just as animals can only arise from animals and plants from plants." This *cell doctrine*, proposed by the German pathologist Rudolf Virchow in 1858, carried with it a profound message for the continuity of life. Cells are generated from cells, and the only way to make more cells is by division of those that already exist. All living organisms, from the unicellular bacterium to the multicellular mammal, are products of repeated rounds of cell growth and division extending back in time to the beginnings of life on Earth over three billion years ago.

A cell reproduces by performing an orderly sequence of events in which it duplicates its contents and then divides in two. This cycle of duplication and division, known as the cell cycle, is the essential mechanism by which all living things reproduce. In unicellular species, such as bacteria and yeasts, each cell division produces a complete new organism. In multicellular species, long and complex sequences of cell divisions are required to produce a functioning organism. Even in the adult body, cell division is usually needed to replace cells that die. In fact, each of us must manufacture many millions of cells every second simply to survive: if all cell division were stopped—by exposure to a very large dose of x-rays, for example—we would die within a few days.

The details of the cell cycle vary from organism to organism and at different times in an organism's life. Certain characteristics, however, are universal. The minimum set of processes that a cell has to perform are those that allow it to accomplish its most fundamental task: the passing on of its genetic information to the next generation of cells. To produce two genetically identical daughter cells, the DNA in each chromosome must first be faithfully replicated to produce two complete copies, and the replicated chromosomes must then be accurately distributed (*segregated*) to the two daughter cells, so that each receives a copy of the entire genome (Figure 17-1).

Eucaryotic cells have evolved a complex network of regulatory proteins, known as the cell-cycle control system, that governs progression through the cell cycle. The core of this system is an ordered series of biochemical switches that control the main events of the cycle, including DNA replication and the

segregation of the replicated chromosomes. In most cells, additional layers of regulation enhance the fidelity of cell division and allow the control system to respond to various signals from both inside and outside the cell. Inside the cell, the control system monitors progression through the cell cycle and delays later events until earlier events have been completed. Preparations for the segregation of replicated chromosomes, for example, are not permitted until DNA replication is complete. The control system also monitors conditions outside the cell. In a multicellular animal, the system is highly responsive to signals from other cells, stimulating cell division when more cells are needed and blocking it when they are not. The cell-cycle control system therefore has a central role in regulating cell numbers in the tissues of the body. When the system malfunctions, excessive cell divisions can result in cancer.

In addition to duplicating their genome, most cells also duplicate their other organelles and macromolecules; otherwise, they would get smaller with each division. To maintain their size, dividing cells must coordinate their growth (i. e., their increase in cell mass) with their division; it is still not clear how this coordination is achieved.

This chapter is concerned primarily with how the various events of the cell cycle are controlled and coordinated. We begin with a brief overview of these events, the molecular details of which are discussed in other chapters (DNA replication in [Chapter 5](#); chromosome segregation and cell division in [Chapter 18](#)). We then describe the cell-cycle control system, examining how it organizes the sequence of cell-cycle events and how it responds to intracellular signals to regulate cell division. We next discuss how multicellular organisms eliminate unwanted cells by the process of *programmed cell death*, or *apoptosis*, in which a cell commits suicide when the interests of the organism demand it. Finally, we consider how animals regulate cell numbers and cell size—using extracellular signals to control cell survival, cell growth, and cell division. [↑ TOP](#)

Molecular Biology of the Cell → IV. Internal Organization of the Cell → 17. The Cell Cycle and Programmed Cell Death

An Overview of the Cell Cycle

The most basic function of the cell cycle is to duplicate accurately the vast amount of DNA in the chromosomes and then segregate the copies precisely into two genetically identical daughter cells. These processes define the two major *phases* of the cell cycle. DNA duplication occurs during *S phase* (S for synthesis), which requires 10–12 hours and occupies about half of the cell-cycle time in a typical mammalian cell. After S phase, chromosome segregation and cell division occur in *M phase* (M for *mitosis*), which requires much less time (less than an hour in a mammalian cell). M phase involves a series of dramatic events that begin with nuclear division, or mitosis. As discussed in detail in [Chapter 18](#), mitosis begins with chromosome condensation: the duplicated DNA strands, packaged into elongated chromosomes, condense into the much more compact chromosomes required for their segregation. The nuclear envelope then breaks down, and the replicated chromosomes, each consisting of a pair of *sister chromatids*, become attached to the microtubules of the *mitotic spindle*. As mitosis proceeds, the cell pauses briefly in a state called *metaphase*, when the chromosomes are aligned at the equator of the mitotic spindle, poised for segregation. The sudden separation of sister chromatids marks the beginning of *anaphase*, during which the chromosomes move to opposite poles of the spindle, where they decondense and reform intact nuclei. The cell is then pinched in two by cytoplasmic division, or *cytokinesis*, and cell division is complete ([Figure 17-2](#)).

Most cells require much more time to grow and double their mass of proteins and organelles than they require to replicate their DNA and divide. Partly to allow more time for growth, extra *gap phases* are inserted in most cell cycles—a **G₁ phase** between M phase and S phase and a **G₂ phase** between S

phase and mitosis. Thus, the eucaryotic cell cycle is traditionally divided into four sequential phases: G₁, S, G₂, and M ([Figure 17-3](#)). G₁, S, and G₂ together are called *interphase*. In a typical human cell proliferating in culture, interphase might occupy 23 hours of a 24 hour cycle, with 1 hour for M phase.

The two gap phases serve as more than simple time delays to allow cell

growth. They also provide time for the cell to monitor the internal and external environment to ensure that conditions are suitable and preparations are complete before the cell commits itself to the major upheavals of S phase and mitosis. The G_1 phase is especially important in this respect. Its length can vary greatly depending on external conditions and extracellular signals from other cells. If extracellular conditions are unfavorable, for example, cells delay progress through G_1 and may even enter a specialized resting state known as G_0 (G zero), in which they can remain for days, weeks, or even years before resuming proliferation. Indeed, many cells remain permanently in G_0 until they or the organism dies. If extracellular conditions are favorable and signals to grow and divide are present, cells in early G_1 or G_0 progress through a commitment point near the end of G_1 known as **Start** (in yeasts) or the restriction point (in mammalian cells). After passing this point, cells are committed to DNA replication, even if the extracellular signals that stimulate cell growth and division are removed.

The Cell-Cycle Control System Is Similar in All Eucaryotes

Some features of the cell cycle, including the time required to complete certain events, vary greatly from one cell type to another, even in the same organism. The basic organization of the cycle and its control system, however, are essentially the same in all eucaryotic cells. The proteins of the control system first appeared over a billion years ago. Remarkably, they have been so well conserved over the course of evolution that many of them function perfectly when transferred from a human cell to a yeast cell. We can therefore study the cell cycle and its regulation in a variety of organisms and use the findings from all of them to assemble a unified picture of how eucaryotic cells divide. In the following section, we briefly review the three eucaryotic systems in which cell-cycle control is commonly studied—yeasts, frog embryos, and cultured mammalian cells. [↑ TOP](#)

The Cell-Cycle Control System Can Be Dissected Genetically in Yeasts

Yeasts are tiny, single-celled fungi whose mechanisms of cell-cycle control are remarkably similar to our own. Two species are generally used in studies of the cell cycle. The fission yeast *Schizosaccharomyces pombe* is named after the African beer it is used to produce. It is a rod-shaped cell that grows by elongation at its ends. Division occurs by the formation of a septum, or cell plate, in the center of the rod ([Figure 17-4A](#)). The budding yeast *Saccharomyces cerevisiae* is used by brewers, as well as by bakers. It is an oval cell that divides by forming a bud, which first appears during G_1 and grows steadily until it separates from the mother cell after mitosis ([Figure 17-](#)

4B).

Despite their outward differences, the two yeast species share a number of features that are extremely useful for genetic studies. They reproduce almost as rapidly as bacteria and have a genome size less than 1% that of a mammal. They are amenable to rapid molecular genetic manipulation, whereby genes can be deleted, replaced, or altered. Most importantly, they have the unusual ability to proliferate in a *haploid* state, in which only a single copy of each gene is present in the cell. When cells are haploid, it is easy to isolate and study mutations that inactivate a gene, as one avoids the complication of having a second copy of the gene in the cell.

Many important discoveries about cell-cycle control have come from systematic searches for mutations in yeasts that inactivate genes encoding essential components of the cell-cycle control system. The genes affected by these mutations are known as cell-division-cycle genes, or *cdc* genes. Many of these mutations cause cells to arrest at a specific point in the cell cycle, suggesting that the normal gene product is required to get the cell past this point.

A mutant that cannot complete the cell cycle cannot be propagated. Thus, *cdc* mutants can be selected and maintained only if their phenotype is *conditional*—that is, if the gene product fails to function only in certain specific conditions. Most conditional cell-cycle mutations are *temperature-sensitive mutations*, in which the mutant protein fails to function at high temperatures but functions well enough to allow cell division at low temperatures. A temperature-sensitive *cdc* mutant can be propagated at a low temperature (the *permissive condition*) and then raised to a higher temperature (the *restrictive condition*) to switch off the function of the mutant gene. At the higher temperature, the cells continue through the cell cycle until they reach the point where the function of the mutant gene is required for further progress, and at this point they halt (Figure 17-5). In budding yeasts, a uniform cell-cycle arrest of this type can be detected by just looking at the cells: the presence or absence of a bud, and bud size, indicate the point in the cycle at which the mutant is arrested (Figure 17-6).  [TOP](#)

The Cell-Cycle Control System Can Be Analyzed Biochemically in Animal Embryos

While yeasts are ideal for studying the genetics of the cell cycle, the biochemistry of the cycle is most easily analyzed in the giant fertilized eggs of many animals, which carry large stockpiles of the proteins needed for cell division. The egg of the frog *Xenopus*, for example, is over 1 mm in diameter and carries 100,000 times more cytoplasm than an average cell in the human body (Figure 17-7). Fertilization of the *Xenopus* egg triggers an astonishingly rapid sequence of cell divisions, called *cleavage divisions*, in which the single giant cell divides, without growing, to generate an embryo containing

thousands of smaller cells (Figure 17-8). In this process, almost the only macromolecules synthesized are DNA—required to produce the thousands of new nuclei—and a small amount of protein. After a first division that takes about 90 minutes, the next 11 divisions occur, more or less synchronously, at 30-minute intervals, producing about 4096 (2^{12}) cells within 7 hours. Each cycle is divided into S and M phases of about 15 minutes each, without detectable G_1 or G_2 phases.

The cells in early embryos of *Xenopus*, as well as those of the clam *Spisula* and the fruit fly *Drosophila*, are thus capable of exceedingly rapid division in the absence of either growth or many of the control mechanisms that operate in more complex cell cycles. These *early embryonic cell cycles* therefore reveal the workings of the cell-cycle control system stripped down and simplified to the minimum needed to achieve the most fundamental requirements—the duplication of the genome and its segregation into two daughter cells. Another advantage of these early embryos for cell-cycle analysis is their large size. It is relatively easy to inject test substances into an egg to determine their effect on cell-cycle progression. It is also possible to prepare almost pure cytoplasm from *Xenopus* eggs and reconstitute many events of the cell cycle in a test tube (Figure 17-9). In such cell extracts, one can observe and manipulate cell-cycle events under highly simplified and controllable conditions. [↑ TOP](#)

The Cell-Cycle Control System of Mammals Can Be Studied in Culture

It is not easy to observe individual cells in an intact mammal. Most studies on mammalian cell-cycle control therefore use cells that have been isolated from normal tissues or tumors and grown in plastic culture dishes in the presence of essential nutrients and other factors (Figure 17-10). There is a complication, however. When cells from normal mammalian tissues are cultured in standard conditions, they often stop dividing after a limited number of division cycles. Human fibroblasts, for example, permanently cease dividing after 25–40 divisions, a process called *replicative cell senescence*, which we discuss later.

Mammalian cells occasionally undergo mutations that allow them to proliferate readily and indefinitely in culture as "immortalized" *cell lines*. Although they are not normal, such cell lines are used widely for cell-cycle studies—and for cell biology generally—because they provide an unlimited source of genetically homogeneous cells. In addition, these cells are sufficiently large to allow detailed cytological observations of cell-cycle events, and they are amenable to biochemical analysis of the proteins involved in cell-cycle control.

Studies of cultured mammalian cells have been especially useful for examining the molecular mechanisms governing the control of cell proliferation in multicellular organisms. Such studies are important not only for understanding the normal controls of cell numbers in tissues but also for understanding the

loss of these controls in cancer (discussed in [Chapter 23](#)). [↑ TOP](#)

Cell-Cycle Progression Can Be Studied in Various Ways

How can one tell at what stage an animal cell is in the cell cycle? One way is to simply look at living cells with a microscope. A glance at a population of mammalian cells proliferating in culture reveals that a fraction of the cells have rounded up and are in mitosis. Others can be observed in the process of cytokinesis. The S-phase cells, however, cannot be detected by simple observation. They can be recognized, however, by supplying them with visualizable molecules that are incorporated into newly synthesized DNA, such as ^3H -thymidine or the artificial thymidine analog bromo-deoxyuridine (BrdU). Cell nuclei that have incorporated ^3H -thymidine are visualized by autoradiography ([Figure 17-11A](#)), whereas those that have incorporated BrdU are visualized by staining with anti-BrdU antibodies ([Figure 17-11B](#)).

Typically, in a population of cells that are all proliferating rapidly but asynchronously, about 30–40% will be in S phase at any instant and become labeled by a brief pulse of ^3H -thymidine or BrdU. From the proportion of cells in such a population that are labeled (the *labeling index*), one can estimate the duration of S phase as a fraction of the whole cell cycle duration. Similarly, from the proportion of these cells in mitosis (the *mitotic index*), one can estimate the duration of M phase. In addition, by giving a pulse of ^3H -thymidine or BrdU and allowing the cells to continue around the cycle for measured lengths of time, one can determine how long it takes for an S-phase cell to progress through G_2 into M phase, through M phase into G_1 , and finally through G_1 back into S phase.

Another way to assess the stage that a cell has reached in the cell cycle is by measuring its DNA content, which doubles during S phase. This approach is greatly facilitated by the use of DNA-binding fluorescent dyes and a *flow cytometer*, which allows large numbers of cells to be analyzed rapidly and automatically ([Figure 17-12](#)). One can also use flow cytometry to determine the lengths of G_1 , S, and $G_2 + \text{M}$ phases, by following over time a population of cells that have been preselected to be in one particular phase of the cell cycle: DNA content measurements on such a synchronized population of cells reveal how the cells progress through the cycle. [↑ TOP](#)

Summary

Cell reproduction begins with duplication of the cell's contents, followed by distribution of those contents into two daughter cells. Chromosome duplication occurs during S phase of the cell cycle, whereas most other cell components are duplicated continuously throughout the cycle. During M phase, the replicated chromosomes are segregated into individual nuclei (mitosis), and

the cell then splits in two (cytokinesis). S phase and M phase are usually separated by gap phases called G_1 and G_2 , when cell-cycle progression can be regulated by various intracellular and extracellular signals. Cell-cycle organization and control have been highly conserved during evolution, and studies in a wide range of systems—including yeasts, frog embryos, and mammalian cells in culture—have led to a unified view of eucaryotic cell-cycle control. Figure 17-2. The events of eucaryotic cell division as seen under a microscope. The easily visible processes of nuclear division (mitosis) and cell division (cytokinesis), collectively called M phase, typically occupy only a small fraction of the cell cycle. The other, much longer, part of the cycle is known as interphase. The five stages of mitosis are shown: an abrupt change in the biochemical state of the cell occurs at the transition from metaphase to anaphase. A cell can pause in metaphase before this transition point, but once the point has been passed, the cell carries on to the end of mitosis and through cytokinesis into interphase. Note that DNA replication occurs in interphase. The part of interphase where DNA is replicated is called S phase (not shown).

Figure 17-4. A comparison of the cell cycles of fission yeasts and budding yeasts. (A) The fission yeast has a typical eucaryotic cell cycle with G_1 , S, G_2 , and M phases. In contrast with what happens in higher eucaryotic cells, however, the nuclear envelope of the yeast cell does not break down during M phase. The microtubules of the mitotic spindle (*light green*) form inside the nucleus and are attached to spindle pole bodies (*dark green*) at its periphery. The cell divides by forming a partition (known as the cell plate) and splitting in two. The condensed mitotic chromosomes (*red*) are readily visible in fission yeast, but are less easily seen in budding yeasts. (B) The budding yeast has normal G_1 and S phases but does not have a normal G_2 phase. Instead, a microtubule-based spindle begins to form inside the nucleus early in the cycle, during S phase. In contrast with a fission yeast cell, the cell divides by budding. As in fission yeasts, but in contrast with higher eucaryotic cells, the nuclear envelope remains intact during mitosis, and the spindle forms within the nucleus.

Figure 17-8. Oocyte growth and egg cleavage in *Xenopus*. The oocyte grows without dividing for many months in the ovary of the mother frog and finally matures into an egg. Upon fertilization, the egg cleaves very rapidly—initially at a rate of one division cycle every 30 minutes—forming a multicellular tadpole within a day or two. The cells get progressively smaller with each division, and the embryo remains the same size. Growth starts only when the tadpole begins feeding. The drawings in the top row are all on the same scale (but the frog below is not).

Figure 17-9. Studying the cell cycle in a cell-free system. A large batch of activated frog eggs is broken open by gentle centrifugation, which also separates the cytoplasm from other cell components. The undiluted cytoplasm is collected, and sperm nuclei are added to it, together with ATP. The sperm nuclei decondense and then go through repeated cycles of DNA replication and mitosis, indicating that the cell-cycle control system is operating in this cell-free cytoplasmic extract.

Figure 17-12. Analysis of DNA content with a flow cytometer. This graph shows typical results obtained for a proliferating cell population when the DNA content of its individual cells is determined in a flow cytometer. (A flow cytometer, also called a fluorescence-activated cell sorter, or FACS, can also be used to sort cells according to their fluorescence—see [Figure 8-2](#)). The cells analyzed here were stained with a dye that becomes fluorescent when it binds to DNA, so that the amount of fluorescence is directly proportional to the amount of DNA in each cell. The cells fall into three categories: those that have an unreplicated complement of DNA and are therefore in G_1 phase, those that have a fully replicated complement of DNA (twice the G_1 DNA content) and are in G_2 or M phase, and those that have an intermediate amount of DNA and are in S phase. The distribution of cells in the case illustrated indicates that there are greater numbers of cells in G_1 phase than in $G_2 + M$ phase, showing that G_1 is longer than $G_2 + M$ in this population.

Components of the Cell-Cycle Control System

For many years cell biologists watched the puppet show of DNA synthesis, mitosis, and cytokinesis but had no idea of what lay behind the curtain controlling these events. The cell-cycle control system was simply a black box inside the cell. It was not even clear whether there was a separate control system, or whether the processes of DNA synthesis, mitosis, and cytokinesis somehow controlled themselves. A major breakthrough came in the late 1980s with the identification of the key proteins of the control system, along with the realization that they are distinct from the proteins that perform the processes of DNA replication, chromosome segregation, and so on.

We first consider the basic principles upon which the cell-cycle control system operates. Then we discuss the protein components of the system and how they work together to activate the different phases of the cell cycle.

The Cell-Cycle Control System Triggers the Major Processes of the Cell Cycle

The cell-cycle control system operates much like the control system of an automatic clothes-washing machine. The washing machine functions in a series of stages: it takes in water, mixes it with detergent, washes the clothes, rinses them, and spins them dry. These essential processes of the wash cycle are analogous to the essential processes of the cell cycle—DNA replication, mitosis, and so on. In both cases, a central controller triggers each process in a set sequence (Figure 17-13).

How might one design a control system that safely guides the cell through the events of the cell cycle (or a wash cycle, for that matter)? In principle, one can imagine that the most basic control system should possess the following features:

- A clock, or timer, that turns on each event at a specific time, thus providing a fixed amount of time for the completion of each event.
- A mechanism for initiating events in the correct order; entry into mitosis, for example, must always come after DNA replication.

- A mechanism to ensure that each event is triggered only once per cycle.
- Binary (on/off) switches that trigger events in a complete, irreversible fashion. It would clearly be disastrous, for example, if events like chromosome condensation or nuclear envelope breakdown were initiated but not completed.
- Robustness: backup mechanisms to ensure that the cycle can work properly even when parts of the system malfunction.
- Adaptability, so that the system's behavior can be modified to suit specific cell types or environmental conditions.

We shall see in this chapter that the cell-cycle control system possesses all of these features, and that we are now beginning to understand the molecular mechanisms involved. [↑ TOP](#)

The Control System Can Arrest the Cell Cycle at Specific Checkpoints

We can illustrate the importance of an adjustable cell-cycle control system by extending our washing machine analogy. The control system of simple embryonic cell cycles, like the controller in a simple washing machine, is based on a clock. The clock is unaffected by the events it regulates and will progress through the whole sequence of events even if one of those events has not been successfully completed. In contrast, the control system of most cell cycles (and sophisticated washing machines) is responsive to information received back from the processes it is controlling. Sensors, for example, detect the completion of DNA synthesis (or the successful filling of the washtub), and, if some malfunction prevents the successful completion of this process, signals are sent to the control system to delay progression to the next phase. These delays provide time for the machinery to be repaired and also prevent the disaster that might result if the cycle progressed prematurely to the next stage.

In most cells there are several points in the cell cycle, called checkpoints, at which the cycle can be arrested if previous events have not been completed (Figure 17-14). Entry into mitosis is prevented, for example, when DNA replication is not complete, and chromosome separation in mitosis is delayed if some chromosomes are not properly attached to the mitotic spindle.

Progression through G_1 and G_2 is delayed by braking mechanisms if the DNA in the chromosomes is damaged by radiation or chemicals. Delays at these *DNA damage checkpoints* provide time for the damaged DNA to be repaired, after which the cell-cycle brakes are released and progress resumes.

Checkpoints are important in another way as well. They are points in the cell cycle at which the control system can be regulated by extracellular signals from other cells. These signals—which can either promote or inhibit cell

proliferation—tend to act by regulating progression through a G_1 checkpoint, using mechanisms discussed later in the chapter. [↑ TOP](#)

Checkpoints Generally Operate Through Negative Intracellular Signals

Checkpoint mechanisms like those just described tend to act through negative intracellular signals that arrest the cell cycle, rather than through the removal of positive signals that normally stimulate cell-cycle progression. The following argument suggests why this is so.

Consider, for example, the checkpoint that monitors the attachment of chromosomes to the mitotic spindle. If a cell proceeds into anaphase and starts to segregate its chromosomes into separate daughter cells before all chromosomes are appropriately attached, one daughter receives an incomplete chromosome set, while the other daughter receives a surplus. The cell therefore needs to be able to detect the attachment of the last unattached chromosome to the microtubules of the spindle. In a cell with many chromosomes, if each chromosome sends a positive signal to the cell-cycle control system once it is attached, the attachment of the last chromosome will be hard to detect, as it will be signaled by only a small fractional change in the total intensity of the "go" signal. On the other hand, if each unattached chromosome sends a negative signal to inhibit progress through the cell cycle, the attachment of the last chromosome will be easily detected because it will cause a change from some "stop" signal to none. A similar argument would imply that unreplicated DNA inhibits the initiation of mitosis, creating a stop signal that persists until the completion of DNA replication.

The most convincing evidence that checkpoints operate through negative signals comes from studies of cells in which a checkpoint is inactivated by either mutation or chemical treatment. In these cells, the cell cycle continues to progress even if DNA replication or spindle assembly is incomplete, indicating that checkpoints are generally not essential for cell-cycle progression. Checkpoints are best viewed as accessory braking systems that have been added to the cell-cycle control system to provide a more sophisticated form of regulation.

Although most checkpoints are not essential for normal cell-cycle progression under ideal conditions, populations of cells with checkpoint defects often accumulate mutations due to occasional malfunctions in DNA replication, DNA repair, or spindle assembly. Some of these mutations can promote the development of cancer, as we discuss later and in [Chapter 23](#). [↑ TOP](#)

The Cell-Cycle Control System Is Based on Cyclically Activated Protein Kinases

At the heart of the cell-cycle control system is a family of protein kinases known as **cyclin-dependent kinases (Cdks)**. The activity of these kinases rises and falls as the cell progresses through the cycle. The oscillations lead directly to cyclical changes in the phosphorylation of intracellular proteins that initiate or regulate the major events of the cell cycle—DNA replication, mitosis, and cytokinesis. An increase in Cdk activity at the beginning of mitosis, for example, leads to increased phosphorylation of proteins that control chromosome condensation, nuclear envelope breakdown, and spindle assembly.

Cyclical changes in Cdk activity are controlled by a complex array of enzymes and other proteins. The most important of these Cdk regulators are proteins known as cyclins. Cdks, as their name implies, are dependent on cyclins for their activity: unless they are tightly bound to a cyclin, they have no protein kinase activity (Figure 17-15). Cyclins were originally named as such because they undergo a cycle of synthesis and degradation in each cell cycle. Cdk levels, by contrast, are constant, at least in the simplest cell cycles. Cyclical changes in cyclin levels result in the cyclic assembly and activation of the **cyclin-Cdk complexes**; this activation in turn triggers cell-cycle events (Figure 17-16).

There are four classes of cyclins, each defined by the stage of the cell cycle at which they bind Cdks and function. Three of these classes are required in all eucaryotic cells:

1. **G₁/S-cyclins** bind Cdks at the end of G₁ and commit the cell to DNA replication.
2. **S-cyclins** bind Cdks during S phase and are required for the initiation of DNA replication.
3. M-cyclins promote the events of mitosis.

In most cells, a fourth class of cyclins, the **G₁-cyclins**, helps promote passage through Start or the restriction point in late G₁.

In yeast cells, a single Cdk protein binds all classes of cyclins and drives all cell-cycle events by changing cyclin partners at different stages of the cycle. In vertebrate cells, by contrast, there are four Cdks. Two interact with G₁-cyclins, one with G₁/S- and S-cyclins, and one with M-cyclins. In this chapter, we simply refer to the different cyclin-Cdk complexes as **G₁-Cdk**, **G₁/S-Cdk**, S-Cdk, and **M-Cdk**. The names of the individual Cdks and cyclins are given in Table 17-1.

How do different cyclin-Cdk complexes drive different cell-cycle events? The answer, at least in part, seems to be that the cyclin protein does not simply activate its Cdk partner but also directs it to specific target proteins. As a result, each cyclin-Cdk complex phosphorylates a different set of substrate proteins. The same cyclin-Cdk complex can also induce different effects at different times in the cycle, probably because the accessibility of some Cdk substrates changes during the cell cycle. Certain proteins that function in mitosis, for example, may become available for phosphorylation only in G₂.

Studies of the three-dimensional structures of Cdk and cyclin proteins have revealed that, in the absence of cyclin, the active site in the Cdk protein is partly obscured by a slab of protein, like a stone blocking the entrance to a cave ([Figure 17-17A](#)). Cyclin binding causes the slab to move away from the active site, resulting in partial activation of the Cdk enzyme ([Figure 17-17B](#)). Full activation of the cyclin-Cdk complex then occurs when a separate kinase, the **Cdk-activating kinase (CAK)**, phosphorylates an amino acid near the entrance of the Cdk active site. This causes a small conformational change that further increases the activity of the Cdk, allowing the kinase to phosphorylate its target proteins effectively and thereby induce specific cell-cycle events ([Figure 17-17C](#)). [↑ TOP](#)

Cdk Activity Can Be Suppressed Both by Inhibitory Phosphorylation and by Inhibitory Proteins

The rise and fall of cyclin levels is the primary determinant of Cdk activity during the cell cycle. Several additional mechanisms, however, are important for fine-tuning Cdk activity at specific stages in the cell cycle.

The activity of a cyclin-Cdk complex can be inhibited by phosphorylation at a pair of amino acids in the roof of the active site. Phosphorylation of these sites by a protein kinase known as **Wee1** inhibits Cdk activity, while dephosphorylation of these sites by a phosphatase known as **Cdc25** increases Cdk activity ([Figure 17-18](#)). We see later that this regulatory mechanism is particularly important in the control of M-Cdk activity at the onset of mitosis.

Cyclin-Cdk complexes can also be regulated by the binding of **Cdk inhibitor proteins (CKIs)**. There are a variety of CKI proteins, and they are primarily employed in the control of G₁ and S phase. The three-dimensional structure of a cyclin-Cdk-CKI complex reveals that CKI binding dramatically rearranges the structure of the Cdk active site, rendering it inactive ([Figure 17-19](#)). [↑ TOP](#)

The Cell-Cycle Control System Depends on Cyclical Proteolysis

Cell-cycle control depends crucially on at least two distinct enzyme complexes that act at different times in the cycle to cause the proteolysis of key proteins of the cell-cycle control system, thereby inactivating them. Most notably, cyclin-Cdk complexes are inactivated by regulated proteolysis of cyclins at certain cell-cycle stages. This cyclin destruction occurs by a ubiquitin-dependent mechanism, like that involved in the proteolysis of many other intracellular proteins (discussed in [Chapter 6](#)). An activated enzyme complex recognizes specific amino-acid sequences on the cyclin and attaches multiple copies of ubiquitin to it, marking the protein for complete destruction in proteasomes.

The rate-limiting step in cyclin destruction is the final ubiquitin-transfer reaction catalyzed by enzymes known as ubiquitin ligases (see [Figure 6-87B](#)). Two ubiquitin ligases are important in the destruction of cyclins and other cell-cycle regulators. In G_1 and S phase, an enzyme complex called *SCF* (after its three main protein subunits) is responsible for the ubiquitylation and destruction of G_1 /S-cyclins and certain CKI proteins that control S-phase initiation. In M phase, the *anaphase-promoting complex* (*APC*) is responsible for the ubiquitylation and proteolysis of M-cyclins and other regulators of mitosis.

These two large, multisubunit complexes contain some related components, but they are regulated in different ways. SCF activity is constant during the cell cycle. Ubiquitylation by SCF is controlled by changes in the phosphorylation state of its target proteins: only specifically phosphorylated proteins are recognized, ubiquitylated, and destroyed ([Figure 17-20A](#)). APC activity, by contrast, changes at different stages of the cell cycle. APC is turned on mainly by the addition of activating subunits to the complex ([Figure 17-20B](#)). We discuss the functions of SCF and APC in more detail later. [↑ TOP](#)

Cell-Cycle Control Also Depends on Transcriptional Regulation

In the frog embryonic cell cycle discussed earlier, gene transcription does not occur. Cell-cycle control depends exclusively on post-transcriptional mechanisms that involve the regulation of Cdk activity by phosphorylation and the binding of regulatory proteins such as cyclins, which are themselves regulated by proteolysis. In the more complex cell cycles of most cell types, however, transcriptional control provides an added level of regulation. Cyclin levels in most cells, for example, are controlled not only by changes in cyclin degradation but also by changes in cyclin gene transcription and cyclin synthesis.

In certain organisms, such as budding yeasts, one can use DNA arrays (discussed in [Chapter 8](#)) to analyze changes in the expression of all of the genes in the genome as the cell progresses through the cell cycle. The results

of these studies are surprising. About 10% of the yeast genes encode mRNAs whose levels oscillate during the cell cycle. Some of these genes encode proteins with known cell-cycle functions, but the functions of many others are unknown. It seems likely that these oscillations in gene expression are controlled by the cyclin-Cdk-dependent phosphorylation of gene regulatory proteins, but the details of this regulation remain unknown. [↑ TOP](#)

Summary

Events of the cell cycle are triggered by an independent cell-cycle control system, which ensures that the events are properly timed, occur in the correct order, and occur only once per cell cycle. The control system is responsive to various intracellular and extracellular signals, so that cell-cycle progression can be arrested when the cell either fails to complete an essential cell-cycle process or encounters unfavorable environmental conditions.

The central components of the cell-cycle control system are cyclin-dependent protein kinases (Cdks), whose activity depends on association with regulatory subunits called cyclins. Oscillations in the activities of various cyclin-Cdk complexes leads to the initiation of various cell-cycle events. Thus, activation of S-phase cyclin-Cdk complexes initiates S phase, while activation of M-phase cyclin-Cdk complexes triggers mitosis. The activities of cyclin-Cdk complexes are influenced by several mechanisms, including phosphorylation of the Cdk subunit, the binding of special inhibitory proteins (CKIs), proteolysis of cyclins, and changes in the transcription of genes encoding Cdk regulators. Two enzyme complexes, SCF and APC, are also crucial components of the cell-cycle control system; they induce the proteolysis of specific cell-cycle regulators by ubiquitylating them and thereby trigger several critical events in the cycle. Intracellular Control of Cell-Cycle Events

Each of the different cyclin-Cdk complexes serves as a molecular switch that triggers a specific cell-cycle event. We now consider how these switches initiate such events and how the cell-cycle control system ensures that the switches fire in the correct order and only once per cell cycle. We begin with the two central events of the cell cycle: the replication of DNA during S phase and the chromosome segregation and cell division of M phase. We then discuss how crucial regulatory mechanisms in G_1 phase control whether or not a cell proliferates.

S-Phase Cyclin-Cdk Complexes (S-Cdks) Initiate DNA Replication Once Per Cycle

A cell must solve several problems in controlling the initiation and completion of DNA replication. Not only must replication occur with extreme accuracy to minimize the risk of mutations in the next cell generation, but every nucleotide in the genome must be copied once, and only once, to prevent the damaging effects of gene amplification. In [Chapter 5](#), we discuss the sophisticated protein machinery that performs DNA replication with astonishing speed and accuracy. In this chapter, we consider the elegant mechanisms by which the cell-cycle control system initiates the replication process and, at the same time, prevents it from happening more than once per cycle.

Early clues about the regulation of S phase came from studies in which human cells at various cell-cycle stages were fused to form single cells with two nuclei. These experiments revealed that when a G_1 cell is fused with an S-phase cell, DNA replication occurs in the G_1 nucleus (presumably triggered by S-Cdk activity in the S-phase cell). Fusion of a G_2 cell with an S-phase cell, however, does not cause DNA synthesis in the G_2 nucleus ([Figure 17-21](#)). These studies provided a clear hint that only G_1 cells are competent to initiate DNA replication and that cells that have completed S phase (i.e. G_2 cells) are not able to rereplicate their DNA, even when provided with S-Cdk activity.

Apparently, passage through mitosis is required for the cell to regain the ability to undergo S phase.

We have begun to decipher the molecular basis of these cell fusion experiments only recently. DNA replication begins at *origins of replication*, which are scattered at various locations in the chromosome. Replication origins are simple and well defined in the budding yeast *S. cerevisiae*, and most of our understanding of the initiation machinery comes from studies of this organism. Analyses of proteins that bind to the yeast replication origin have identified a large, multiprotein complex known as the **origin recognition complex (ORC)**. These complexes bind to replication origins throughout the cell cycle and serve as landing pads for several additional regulatory proteins.

One of these regulatory proteins is **Cdc6**. It is present at low levels during most of the cell cycle but increases transiently in early G₁. It binds to ORC at replication origins in early G₁, where it is required for the binding of a complex composed of a group of closely related proteins, the Mcm proteins. The resulting large protein complex formed at an origin is known as the **pre-replicative complex**, or **pre-RC** (Figure 17-22).

Once the pre-RC has been assembled in G₁, the replication origin is ready to fire. The activation of S-Cdk in late G₁ pulls the trigger and initiates DNA replication. The initiation of replication also requires the activity of a second protein kinase, which collaborates with S-Cdk to cause the phosphorylation of ORC.

The S-Cdk not only initiates origin firing, but also helps to prevent rereplication in several ways. First, it causes the Cdc6 protein to dissociate from ORC after an origin has fired. This results in the disassembly of the pre-RC, which prevents replication from occurring again at the same origin. Second, it prevents the Cdc6 and Mcm proteins from reassembling at any origin. By phosphorylating Cdc6, it triggers Cdc6 ubiquitylation by the SCF enzyme complex discussed earlier. As a result, any Cdc6 protein that is not bound to an origin is rapidly degraded in proteasomes. S-Cdk also phosphorylates certain Mcm proteins, which triggers their export from the nucleus, further ensuring that the Mcm protein complex cannot bind to a replication origin (see Figure 17-22).

S-Cdk activity remains high during G₂ and early mitosis, preventing rereplication from occurring after the completion of S phase. M-Cdk also helps ensure that rereplication does not occur during mitosis by phosphorylating the Cdc6 and Mcm proteins. The G₁/S-Cdks help as well, by inducing Mcm export from the nucleus, ensuring that excess Mcm proteins that have not bound to origins in late G₁ are taken out of action before replication begins.

Thus, several cyclin-Cdk complexes cooperate to restrain pre-RC assembly and prevent DNA rereplication after S phase. How, then, is the cell-cycle control system reset to allow replication to occur in the next cell cycle? The answer is simple. At the end of mitosis, all Cdk activity in the cell is reduced to zero. The resulting dephosphorylation of the Cdc6 and Mcm proteins allows pre-RC assembly to occur once again, readying the chromosomes for a new round of replication. [↑ TOP](#)

The Activation of M-Phase Cyclin-Cdk Complexes (M-Cdks) Triggers Entry into Mitosis

The completion of DNA replication leaves the G_2 cell with two accurate copies of the entire genome, with each replicated chromosome consisting of two identical *sister chromatids* glued together along their length. The cell then undergoes the dramatic upheaval of M phase, in which the duplicated chromosomes and other cell contents are distributed equally to the two daughter cells. The events of mitosis are triggered by M-Cdk, which is activated after S phase is complete.

The activation of M-Cdk begins with the accumulation of M-cyclin (cyclin B in vertebrate cells, see [Table 17-1](#)). In embryonic cell cycles, the synthesis of M-cyclin is constant throughout the cell cycle, and M-cyclin accumulation results from a decrease in its degradation. In most cell types, however, M-cyclin synthesis increases during G_2 and M, owing primarily to an increase in *M-cyclin* gene transcription. This increase in M-cyclin protein leads to a gradual accumulation of M-Cdk (the complex of Cdk1 and M-cyclin) as the cell approaches mitosis. Although the Cdk in these complexes is phosphorylated at an activating site by the enzyme CAK discussed earlier, it is held in an inactive state by inhibitory phosphorylation at two neighboring sites by the protein kinase Wee1 (see [Figure 17-18](#)). Thus, by the time the cell reaches the end of G_2 , it contains an abundant stockpile of M-Cdk that is primed and ready to act, but the M-Cdk activity is repressed by the presence of two phosphate groups that block the active site of the kinase.

What, then, triggers the activation of the M-Cdk stockpile? The crucial event is the activation in late G_2 of the protein phosphatase Cdc25, which removes the inhibitory phosphates that restrain M-Cdk ([Figure 17-23](#)). At the same time, the activity of the inhibitory kinase Wee1 is also suppressed, further ensuring that M-Cdk activity increases abruptly. Two protein kinases activate Cdc25. One, known as **Polo kinase**, phosphorylates Cdc25 at one set of sites. The other activating kinase is M-Cdk itself, which phosphorylates a different set of sites on Cdc25. M-Cdk also phosphorylates and inhibits Wee1.

The ability of M-Cdk to activate its own activator (Cdc25) and inhibit its own inhibitor (Wee1) suggests that M-Cdk activation in mitosis involves a positive

feedback loop (see [Figure 17-23](#)). According to this attractive model, the partial activation of Cdc25, perhaps by Polo kinase, leads to the partial activation of a subpopulation of M-Cdk complexes, which then phosphorylate more Cdc25 and Wee1 molecules. This leads to more M-Cdk dephosphorylation and activation, and so on. Such a mechanism would quickly promote the complete activation of all the M-Cdk complexes in the cell, converting a gradual increase in M-cyclin levels into a switchlike, abrupt rise in M-Cdk activity. As mentioned earlier, similar molecular switches operate at various points in the cell cycle to ensure that events such as entry into mitosis occur in an all-or-none fashion. [↑ TOP](#)

Entry into Mitosis Is Blocked by Incomplete DNA Replication: The DNA Replication Checkpoint

If a cell is driven into mitosis before it has finished replicating its DNA, it will pass on broken or incomplete sets of chromosomes to its daughter cells. This disaster is avoided in most cells by a **DNA replication checkpoint** mechanism, which ensures that the initiation of mitosis cannot occur until the last nucleotide in the genome has been copied. Sensor mechanisms, of unknown molecular nature, detect either the unreplicated DNA or the corresponding unfinished replication forks and send a negative signal to the cell-cycle control system, blocking the activation of M-Cdk. Thus, normal cells treated with chemical inhibitors of DNA synthesis, such as hydroxyurea, do not progress into mitosis. If the checkpoint mechanism is defective, however, as in yeast cells with certain mutations or in mammalian cells treated with high doses of caffeine, the cells plunge into a suicidal mitosis despite the failure to complete DNA replication ([Figure 17-24](#)).

The final targets of the negative checkpoint signal are the enzymes that control M-Cdk activation. The negative signal activates a protein kinase that inhibits the Cdc25 protein phosphatase (see [Figures 17-18](#) and [17-23](#)). As a result, M-Cdk remains phosphorylated and inactive until DNA replication is complete. [↑ TOP](#)

M-Cdk Prepares the Duplicated Chromosomes for Separation

One of the most remarkable features of cell-cycle control is that a single protein kinase, M-Cdk, is able to bring about all of the diverse and complex rearrangements that occur in the early stages of mitosis (discussed in [Chapter 18](#)). At a minimum, M-Cdk must induce the assembly of the mitotic spindle and ensure that replicated chromosomes attach to the spindle. In many organisms, M-Cdk also triggers chromosome condensation, nuclear envelope breakdown, actin cytoskeleton rearrangement, and the reorganization of the Golgi apparatus and endoplasmic reticulum. Each of these events is thought to be triggered when M-Cdk phosphorylates specific structural or regulatory

proteins involved in the event, although most of these proteins have not yet been identified.

The breakdown of the nuclear envelope, for example, requires the disassembly of the *nuclear lamina*—the underlying shell of polymerized lamin filaments that gives the nuclear envelope its structural rigidity. Direct phosphorylation of lamin proteins by M-Cdk results in their depolymerization, which is an essential first step in the dismantling of the envelope (see [Figure 12-21](#)).

Chromosome condensation also seems to be a direct consequence of phosphorylation by M-Cdk. A complex of five proteins, known as the **condensin complex**, is required for chromosome condensation in *Xenopus* embryos. After M-Cdk has phosphorylated several subunits in the complex, two of the subunits are able to change the coiling of DNA molecules in a test tube. It is thought that this coiling activity is important for chromosome condensation during mitosis (see [Figure 4-56](#)).

Phosphorylation by M-Cdk also triggers the complex microtubule rearrangements and other events that lead to the assembly of the mitotic spindle. As discussed in [Chapter 18](#), M-Cdk is known to phosphorylate a number of proteins that regulate microtubule behavior, causing the increase in microtubule instability that is required for spindle assembly. [↑ TOP](#)

Sister Chromatid Separation Is Triggered by Proteolysis

After M-Cdk has triggered the complex rearrangements that occur in early mitosis, the cell cycle reaches its culmination with the separation of the **sister chromatids** at the *metaphase-to-anaphase transition*. Although M-Cdk activity sets the stage for this event, an entirely different enzyme complex—the **anaphase-promoting complex (APC)** introduced earlier—throws the switch that initiates sister-chromatid separation. The APC is a highly regulated ubiquitin ligase that promotes the destruction of several mitotic regulatory proteins (see [Figure 17-20B](#)).

The attachment of the two sister chromatids to opposite poles of the mitotic spindle early in mitosis results in forces tending to pull the two chromatids apart. These pulling forces are initially resisted because the sister chromatids are bound tightly together, both at their centromeres and all along their arms. This sister-chromatid cohesion depends on a complex of proteins, the **cohesin complex**, that is deposited along the chromosomes as they are duplicated in S phase. The cohesin proteins (*cohesins*) are closely related to the proteins of the condensin complex involved in chromosome condensation, suggesting a common evolutionary origin for the two processes (see [Figure 18-3](#)).

Anaphase begins with a sudden disruption of the cohesion between sister chromatids, which allows them to separate and move to opposite poles of the spindle. This process is initiated by a remarkable cascade of signaling events.

The sister-chromatid separation requires the activation of the APC enzyme complex, suggesting that proteolysis is central to the process ([Figure 17-25](#)). The relevant target of the APC is the protein **securin**. Before anaphase, securin binds to and inhibits the activity of a protease called **separase**. The destruction of securin at the end of metaphase releases separase, which is then free to cleave one of the subunits of the cohesin complex. In an instant, the cohesin complex falls away from the chromosomes, and the sister chromatids separate ([Figure 17-26](#)).

If the APC triggers anaphase, what triggers the APC? The answer is only partly known. APC activation requires the protein **Cdc20**, which binds to and activates the APC at mitosis (see [Figures 17-26](#) and [17-20B](#)). At least two processes regulate Cdc20 and its association with the APC. First, Cdc20 synthesis increases as the cell approaches mitosis, owing to an increase in the transcription of its gene. Second, phosphorylation of the APC helps Cdc20 bind to the APC, thereby helping to create an active complex.

It is not clear what kinases phosphorylate and activate the Cdc20-APC complex. M-Cdk activity is required for the activity of these kinases, but there is a significant delay, or *lag phase*, between M-Cdk activation and the activation of the Cdc20-APC complex. The molecular basis of this delay is still mysterious, but it is likely to hold the key to how anaphase is initiated at the correct time in M phase. [↑ TOP](#)

Unattached Chromosomes Block Sister-Chromatid Separation: The Spindle-Attachment Checkpoint

The cell does not commit itself to the momentous events of anaphase before it is fully prepared. In most cell types, a spindle-attachment checkpoint mechanism operates to ensure that all chromosomes are properly attached to the spindle before sister-chromatid separation occurs. The checkpoint depends on a sensor mechanism that monitors the state of the *kinetochore*, the specialized region of the chromosome that attaches to microtubules of the spindle. Any kinetochore that is not properly attached to the spindle sends out a negative signal to the cell-cycle control system, blocking Cdc20-APC activation and sister-chromatid separation.

The nature of the signal generated by an unattached kinetochore is not clear, although several proteins, including *Mad2*, are recruited to unattached kinetochores and are required for the spindle-attachment checkpoint to function. Even a single unattached kinetochore in the cell results in *Mad2* binding and the inhibition of Cdc20-APC activity and Securin destruction ([Figure 17-27](#)). Thus, sister-chromatid separation cannot occur until the last kinetochore is attached.

Surprisingly, the normal timing of anaphase does not require a functional spindle-attachment checkpoint, at least in frog embryos and yeasts. Mutant

yeast cells with a defective checkpoint undergo anaphase with normal timing, indicating that some other mechanism normally determines the timing of anaphase in these cells. In mammalian cells, however, a defect in the spindle-attachment checkpoint causes anaphase to occur slightly earlier than normal. This finding suggests that, in our cells, the checkpoint has evolved from a useful accessory to an essential component of the cell-cycle control system. [↑ TOP](#)

Exit from Mitosis Requires the Inactivation of M-Cdk

After the chromosomes have been segregated to the poles of the spindle, the cell must reverse the complex changes of early mitosis. The spindle must be disassembled, the chromosomes decondensed, and the nuclear envelope reformed. Because the phosphorylation of various proteins is responsible for getting cells into mitosis in the first place, it is not surprising that the dephosphorylation of these same proteins is required to get them out. In principle, these dephosphorylations and the exit from mitosis could be triggered by the inactivation of M-Cdk, the activation of phosphatases, or both. Evidence suggests that M-Cdk inactivation is primarily responsible.

M-Cdk inactivation occurs mainly by ubiquitin-dependent proteolysis of M-cyclins. Ubiquitylation of the cyclin is usually triggered by the same Cdc20-APC complex that promotes the destruction of Securin at the metaphase-to-anaphase transition (see [Figure 17-20B](#)). Thus, the activation of the Cdc20-APC complex leads not only to anaphase, but also to M-Cdk inactivation—which in turn leads to all of the other events that take the cell out of mitosis. [↑ TOP](#)

The G_1 Phase Is a State of Stable Cdk Inactivity

In early animal embryos, the inactivation of M-Cdk in late mitosis is due almost entirely to the action of Cdc20-APC. Recall, however, that M-Cdk stimulates Cdc20-APC activity (see [Figure 17-26](#)). Thus, the destruction of M-cyclin in late mitosis soon leads to the inactivation of all APC activity in an embryonic cell. This is a useful arrangement in rapid embryonic cell cycles, as APC inactivation immediately after mitosis allows the cell to quickly begin accumulating new M-cyclin for the next cycle ([Figure 17-28A](#)).

Rapid cyclin accumulation immediately after mitosis is not useful, however, in cell cycles containing a G_1 phase. In these cycles, progression into the next S phase is delayed in G_1 to allow for cell growth and for the cycle to be regulated by extracellular signals. Thus, most cells employ several mechanisms to ensure that Cdk reactivation is prevented after mitosis. One mechanism makes use of another APC-activating protein called *Hct1*, a close relative of Cdc20. Although both Hct1 and Cdc20 bind and activate the APC, they differ in one important respect. Whereas the Cdc20-APC complex is

activated by M-Cdk, the Hct1-APC complex is inhibited by M-Cdk, which directly phosphorylates Hct1. As a result of this relationship, Hct1-APC activity increases in late mitosis after the Cdc20-APC complex has initiated the destruction of M-cyclin. M-cyclin destruction therefore continues after mitosis: although Cdc20-APC activity has declined, Hct1-APC activity is high (Figure 17-28B).

A second mechanism that suppresses Cdk activity in G_1 depends on the increased production of CKIs, the Cdk inhibitory proteins discussed earlier. Budding yeast cells, in which this mechanism is best understood, contain a CKI protein called *Sic1*, which binds to and inactivates M-Cdk in late mitosis and G_1 . Like Hct1, *Sic1* is inhibited by M-Cdk, which phosphorylates *Sic1* during mitosis. M-Cdk also phosphorylates and inhibits a gene regulatory protein required for *Sic1* synthesis, resulting in decreased *Sic1* production. Thus, *Sic1* and M-Cdk, like Hct1 and M-Cdk, mutually inhibit each other. As a result, the decline in M-Cdk activity that occurs in late mitosis triggers the rapid accumulation of *Sic1* protein, and this CKI helps ensure that M-Cdk activity is stably inhibited after mitosis.

In most cells, M-Cdk inactivation in late mitosis also results from decreased transcription of M-cyclin genes. In budding yeast, for example, M-Cdk promotes the expression of these genes, resulting in a positive feedback loop. This loop is turned off as cells exit from mitosis: the inactivation of M-Cdk by Hct1 and *Sic1* leads to decreased M-cyclin gene transcription and thus decreased M-cyclin synthesis.

In summary Hct1-APC activation, CKI accumulation, and decreased cyclin production act together to ensure that the early G_1 phase is a time when essentially all Cdk activity is suppressed. As in many other aspects of cell-cycle control, the use of multiple regulatory mechanisms makes the suppression system robust, so that it still operates with reasonable efficiency even if one mechanism fails.

How does the cell escape from this stable G_1 state to initiate S phase? As we describe later, escape usually occurs through the accumulation of G_1 -cyclins. In budding yeast, for example, these cyclins are not targeted for destruction by Hct1-APC and are not inhibited by *Sic1*. As a result, the accumulation of G_1 cyclins leads to an unopposed increase in G_1 -Cdk activity (Figure 17-29). In animal cells, the accumulation of G_1 -cyclins is stimulated by the extracellular signals that promote cell proliferation, as we discuss later.

In budding yeast, G_1 -Cdk activity triggers the transcription of G_1 /S-cyclin genes, leading to increased synthesis of G_1 /S-cyclins and the formation of G_1 /S-Cdk complexes, which are also resistant to Hct1-APC and *Sic1*. The

increased G_1/S -Cdk activity initiates the events that commit the cell to enter S phase. It stimulates the transcription of S-cyclin genes, leading to the synthesis of S-cyclins and the formation of S-Cdk complexes. These complexes are inhibited by Sic1, but G_1/S -Cdk phosphorylates and inactivates Sic1, thereby causing S-Cdk activation. G_1/S -Cdk and S-Cdk also phosphorylate and inactivate Hct1-APC. Thus, the same feedback loops that trigger rapid M-Cdk inactivation in late mitosis now work in reverse at the end of G_1 to ensure the rapid and complete activation of S-Cdk activity. [↑ TOP](#)

The Rb Protein Acts as a Brake in Mammalian G_1 Cells

The control of G_1 progression and S-phase initiation is often disrupted in cancer cells, leading to unrestrained cell-cycle entry and cell proliferation (discussed in [Chapter 23](#)). To develop improved methods for controlling cancer growth, we need a better understanding of the proteins that control G_1 progression in mammalian cells.

Animal cells suppress Cdk activity in G_1 by the same three mechanisms mentioned earlier for budding yeast: Hct1 activation, the accumulation of a CKI protein (p27 in mammalian cells), and the inhibition of cyclin gene transcription. As in yeasts, the activation of G_1 -Cdk complexes reverses all three inhibitory mechanisms in late G_1 .

The best understood effects of G_1 -Cdk activity in animal cells are mediated by a gene regulatory protein called **E2F**. It binds to specific DNA sequences in the promoters of many genes that encode proteins required for S-phase entry, including G_1/S -cyclins and S-cyclins. E2F function is controlled primarily by an interaction with the **retinoblastoma protein (Rb)**, an inhibitor of cell-cycle progression. During G_1 , Rb binds to E2F and blocks the transcription of S-phase genes. When cells are stimulated to divide by extracellular signals, active G_1 -Cdk accumulates and phosphorylates Rb, reducing its affinity for E2F. The Rb then dissociates, allowing E2F to activate S-phase gene expression ([Figure 17-30](#)).

This transcriptional control system, like so many other control systems that regulate the cell cycle, includes feedback loops that sharpen the G_1/S transition (see [Figure 17-30](#)):

- The liberated E2F increases the transcription of its own gene.
- E2F-dependent transcription of G_1/S -cyclin and S-cyclin genes leads to

increased G_1/S -Cdk and S-Cdk activities, which in turn increase Rb phosphorylation and promote further E2F release.

- The increase in G_1/S -Cdk and S-Cdk activities enhances the phosphorylation of Hct1 and p27, leading to their inactivation or destruction.

As in yeast cells, the result of all these interactions is the rapid and complete activation of the S-Cdk complexes required for S-phase initiation.

The Rb protein was identified originally through studies of an inherited form of eye cancer in children, known as *retinoblastoma* (discussed in [Chapter 23](#)). The loss of both copies of the Rb gene leads to excessive cell proliferation in the immature retina, suggesting that the Rb protein is particularly important for restraining the rate of cell division in the developing retina. The complete loss of Rb does not immediately cause increased proliferation of other cell types, in part because Hct1 and p27 provide assistance in G_1 control, and in part

because other cell types contain Rb-related proteins that provide backup support in the absence of Rb. It is also likely that other proteins, unrelated to Rb, help to regulate the activity of E2F. [↑ TOP](#)

Cell-Cycle Progression Is Somehow Coordinated With Cell Growth

For proliferating cells to maintain a relatively constant size, the length of the cell cycle must match the time it takes the cell to double in size. If the cycle time is shorter than this, the cells will get smaller with each division; if it is longer, the cells will get bigger with each division. Because cell growth depends on nutrients and growth signals in the environment, the length of the cell cycle has to be able to adjust to varying environmental conditions ([Figure 17-31](#)). It is not clear how proliferating cells coordinate their growth with the rate of cell-cycle progression to maintain their size.

There is evidence that budding yeasts coordinate their growth and cell-cycle progression by monitoring the total amount of a G_1 cyclin called **Cln3** (see [Table 17-1](#), p. 994). Because Cln3 is synthesized in parallel with cell growth, its concentration remains constant while its total amount increases as the cell grows. If the amount of Cln3 is artificially increased, the cells divide at a smaller size than normal, whereas if it is artificially decreased, the cells divide at a larger size than normal. These experiments are consistent with the idea that the cells commit themselves to division when the total amount of Cln3 reaches some threshold value. How, then, can the cell monitor the total amount of Cln3, rather than its concentration? One possibility is that cells inherit a fixed amount of an inhibitor that can bind to Cln3 and block its activity. When the amount of Cln3 exceeds the amount of this inhibitor, the extra Cln3 triggers G_1 -Cdk activation and a new cell cycle. Since all cells receive a fixed

and equal quantity of DNA, it has been speculated that the Cln3 inhibitor could be DNA itself, or some protein bound to DNA ([Figure 17-32](#)). Such a mechanism would also explain why cell size in all organisms is proportional to ploidy (the number of copies of the nuclear genome per cell).

Whereas yeast cells grow and proliferate constitutively if nutrients are plentiful, animal cells generally grow and proliferate only when they are stimulated to do so by signals from other cells. The size at which an animal cell divides depends, at least in part, on these extracellular signals, which can regulate cell growth and proliferation independently. Animal cells can also completely uncouple cell growth and division so as to grow without dividing or to divide without growing. The eggs of many animals, for example, grow to an extremely large size without dividing. After fertilization, this relationship is reversed, and many rounds of division occur without growth (see [Figure 17-8](#)). Thus, although cell growth and cell division are usually coordinated, they can be regulated independently. Cell growth does not depend on cell-cycle progression. Yeast cells continue to grow when cell-cycle progression is blocked by a mutation; and many animal cells, including neurons and muscle cells, grow large after they have withdrawn permanently from the cell cycle. [↑ TOP](#)

Cell-Cycle Progression is Blocked by DNA Damage and p53: DNA Damage Checkpoints

When chromosomes are damaged, as can occur after exposure to radiation or certain chemicals, it is essential that they be repaired before the cell attempts to duplicate or segregate them. The cell-cycle control system can readily detect DNA damage and arrest the cycle at **DNA damage checkpoints**. Most cells have at least two such checkpoints—one in late G₁, which prevents entry into S phase, and one in late G₂, which prevents entry into mitosis.

The G₂ checkpoint depends on a mechanism similar to the one discussed earlier that delays entry into mitosis in response to incomplete DNA replication. When cells in G₂ are exposed to damaging radiation, for example, the damaged DNA sends a signal to a series of protein kinases that phosphorylate and inactivate the phosphatase Cdc25. This blocks the dephosphorylation and activation of M-Cdk, thereby blocking entry into mitosis. When the DNA damage is repaired, the inhibitory signal is turned off, and cell-cycle progression resumes.

The G₁ checkpoint blocks progression into S phase by inhibiting the activation of G₁/S-Cdk and S-Cdk complexes. In mammalian cells, for example, DNA damage leads to the activation of the gene regulatory protein p53, which stimulates the transcription of several genes. One of these genes encodes a CKI

protein called **p21**, which binds to G₁/S-Cdk and S-Cdk and inhibits their activities, thereby helping to block entry into S phase.

DNA damage activates p53 by an indirect mechanism. In undamaged cells, p53 is highly unstable and is present at very low concentrations. This is because it interacts with another protein, **Mdm2**, that acts as a ubiquitin ligase that targets p53 for destruction by proteasomes. DNA damage activates protein kinases that phosphorylate p53 and thereby reduce its binding to Mdm2. This decreases p53 degradation, which results in a marked increase in p53 concentration in the cell. In addition, the decreased binding to Mdm2 enhances the ability of p53 to stimulate gene transcription ([Figure 17-33](#)).

Like many other checkpoints, DNA damage checkpoints are not essential for normal cell division if environmental conditions are ideal. Conditions are rarely ideal, however: a low level of DNA damage occurs in the normal life of any cell, and this damage accumulates in the cell's progeny if the damage checkpoints are not functioning. Over the long term, the accumulation of genetic damage in cells lacking checkpoints leads to an increased frequency of cancer-promoting mutations. Indeed, mutations in the p53 gene occur in at least half of all human cancers (discussed in [Chapter 23](#)). This loss of p53 function allows the cancer cell to accumulate mutations more readily. Similarly, a rare genetic disease known as *ataxia telangiectasia* is caused by a defect in one of the protein kinases that phosphorylates and activates p53 in response to x-ray-induced DNA damage; patients with this disease are very sensitive to x-rays due to the loss of the DNA damage checkpoints, and they consequently suffer from increased rates of cancer.

What if DNA damage is so severe that repair is not possible? In this case, the response is different in different organisms. Unicellular organisms such as budding yeast transiently arrest their cell cycle to repair the damage. If repair cannot be completed, the cycle resumes despite any damage. For a single-celled organism, life with mutations is apparently better than no life at all. In multicellular organisms, however, the health of the organism takes precedence over the life of an individual cell. Cells that divide with severe DNA damage threaten the life of the organism, since genetic damage can often lead to cancer and other lethal defects. Thus, animal cells with severe DNA damage do not attempt to continue division, but instead commit suicide by undergoing programmed cell death, or apoptosis, as we discuss in the next section. The decision to die in this way also depends on the activation of p53, and it is this function of p53 that is apparently most important in protecting us against cancer.

As a review, the major cell-cycle regulatory proteins are summarized in [Table 17-2](#), with the general structure of the cell-cycle control system shown in [Figure 17-34](#). [↑ TOP](#)

Summary

An ordered sequence of cyclin-Cdk activities triggers most of the events of the cell cycle. During G_1 phase, Cdk activity is reduced to a minimum by Cdk inhibitors (CKIs), cyclin proteolysis, and decreased cyclin gene transcription. When environmental conditions are favorable, G_1 - and G_1/S -Cdks increase in concentration, overcoming these inhibitory barriers in late G_1 and triggering the activation of S-Cdk. The S-Cdk phosphorylates proteins at DNA replication origins, initiating DNA synthesis through a mechanism that ensures that the DNA is duplicated only once per cell cycle.

Once S phase is completed, the activation of M-Cdk leads to the events of early mitosis, whereby the cell assembles a mitotic spindle and prepares for segregation of the duplicated chromosomes—which consist of sister chromatids glued together. Anaphase is triggered by the destruction of the proteins that hold the sisters together. The M-Cdk is then inactivated by cyclin proteolysis, which leads to cytokinesis and the end of M phase. Progression through the cell cycle is regulated precisely by various inhibitory mechanisms that arrest the cell cycle at specific checkpoints when events are not completed successfully, when DNA damage occurs, or when extracellular conditions are unfavorable. Figure 17-21. Evidence from cell-fusion experiments for a rereplication block. These experiments were carried out in 1970 in cultured mammalian cells. (A) The results show that S-phase cytoplasm contains factors that drive a G₁ nucleus directly into DNA synthesis. (B) A G₂ nucleus, having already replicated its DNA, is refractory to these factors. (C) Fusion of a G₂ cell with a G₁ cell does not drive the G₁ nucleus into DNA synthesis, indicating that the cytoplasmic factors for DNA replication that were present in the S-phase cell disappear when the cell moves from S phase into G₂. (Adapted from R.T. Johnson and P.N. Rao, *Nature* 226:717–722, 1970.)

Figure 17-22. The initiation of DNA replication once per cell cycle. The ORC remains associated with a replication origin throughout the cell cycle. In early G_1 , Cdc6 associates with ORC. Aided by Cdc6, Mcm ring complexes then assemble on the adjacent DNA, resulting in the formation of the pre-replicative complex. The S-Cdk (with assistance from another protein kinase, not shown) then triggers origin firing, assembling DNA polymerase and other replication proteins and activating the Mcm protein rings to migrate along DNA strands as DNA helicases. The S-Cdk also blocks rereplication by causing the dissociation of Cdc6 from origins, its degradation, and the export of all excess Mcm out of the nucleus. Cdc6 and Mcm cannot return to reset an ORC-containing origin for another round of DNA replication until M-Cdk has been inactivated at the end of mitosis (see text).

Figure 17-23. The activation of M-Cdk. Cdk1 associates with M-cyclin as the levels of M-cyclin gradually rise. The resulting M-Cdk complex is phosphorylated on an activating site by the Cdk-activating kinase (CAK) and on a pair of inhibitory sites by the Wee1 kinase. The resulting inactive M-Cdk complex is then activated at the end of G_2 by the phosphatase Cdc25. Cdc25 is stimulated in part by Polo kinase, which is not shown for simplicity. Cdc25 is further stimulated by active M-Cdk, resulting in positive feedback. This feedback is enhanced by the ability of M-Cdk to inhibit Wee1.

Figure 17-24. The DNA replication checkpoint. In the experiments diagrammed here, mammalian cells in culture were treated with caffeine and hydroxyurea, either alone or in combination. Hydroxyurea blocks DNA synthesis. This block activates a checkpoint mechanism that arrests the cells in S phase, delaying mitosis. But if caffeine is added as well as hydroxyurea, the checkpoint mechanism fails, and the cells proceed into mitosis according to their normal schedule, with incompletely replicated DNA. As a result, the cells die.

Figure 17-25. Two experiments that demonstrate the requirement for protein degradation to exit from mitosis. (A) An APC inhibitor was added to frog egg extracts undergoing mitosis *in vitro* (see Figure 17-9). The inhibitor arrested mitosis at metaphase, indicating that proteolysis is required for the separation of sister chromatids at the metaphase-to-anaphase transition. A similar arrest occurs in budding yeasts with mutations in components of the APC. (B) A nondegradable mutant form of M-cyclin was added to mitotic frog egg extracts. This addition arrested mitosis after sister-chromatid separation, indicating that destruction of M-cyclin is not required for sister-chromatid separation but is required for the subsequent exit from mitosis. (Based on S.L. Holloway et al., *Cell* 73:1393–1402, 1993.)

Figure 17-26. The triggering of sister-chromatid separation by the APC. The activation of APC by Cdc20 leads to the ubiquitylation and destruction of securin, which normally holds separase in an inactive state. The destruction of securin allows separase to cleave a subunit of the cohesin complex holding the sister chromatids together. The pulling forces of the mitotic spindle then pull the sister chromatids apart. In budding yeasts at least, cohesin cleavage by separase is facilitated by the phosphorylation of the cohesin complex adjacent to the cleavage site, just before anaphase begins. The phosphorylation is mediated by Polo kinase and provides an additional control on the timing of the metaphase-to-anaphase transition.

Figure 17-28. The creation of a G₁ phase by stable Cdk inhibition after mitosis. (A) In early embryonic cell cycles, Cdc20-APC activity rises at the end of metaphase, triggering M-cyclin destruction. Because M-Cdk activity stimulates Cdc20-APC activity, the loss of M-cyclin leads to APC inactivation after mitosis, which allows M-cyclins to begin accumulating again. (B) In cells containing a G₁ phase, the drop in M-Cdk activity in late mitosis leads to the activation of Hct1-APC (as well as to the accumulation of CKI proteins, not shown). This ensures a continued suppression of Cdk activity after mitosis, as required for a G₁ phase.

Figure 17-32. A hypothetical model of how budding yeast cells might coordinate cell growth and cell-cycle progression. The cell contains a fixed number of proteins (*red*) that are bound to DNA and bind and inhibit Cln3 molecules (*green*). As the cell grows, the total number of Cln3 molecules increases in parallel with total cell protein. When the cell is small (*left*), all of the Cln3 is inactivated by the excess of Cln3-binding protein. As the cell grows, however, it reaches a threshold size at which the number of Cln3 molecules equals the number of Cln3-binding proteins (*middle*). When the cell exceeds this size, free Cln3 can bind to Cdk, which can now trigger the next cell cycle (*right*).

Figure 17-33. How DNA damage arrests the cell cycle in G₁. When DNA is damaged, protein kinases that phosphorylate p53 are activated. Mdm2 normally

binds to p53 and promotes its ubiquitylation and destruction in proteasomes. Phosphorylation of p53 blocks its binding to Mdm2; as a result, p53 accumulates to high levels and stimulates transcription of the gene that encodes the CKI protein p21. The p21 binds and inactivates G₁/S-Cdk and S-Cdk complexes, arresting the cell in G₁. In some cases, DNA damage also induces either the phosphorylation of Mdm2 or a decrease in Mdm2 production, which causes an increase in p53 (not shown).

Table 17-2. Summary of the Major Cell-cycle Regulatory Proteins

GENERAL NAME

FUNCTIONS AND COMMENTS

Protein kinases and protein

phosphatases that modify Cdk

Cdk-activating kinase (CAK) phosphorylates an activating site in Cdk

Wee1 kinase

phosphorylates inhibitory sites in Cdk; primarily involved in controlling entry into mitosis

Cdc25 phosphatase

removes inhibitory phosphates from Cdk; three family members (Cdc25A, B, C) in mammals; Cdc25C is the activator of Cdk1 at the onset of mitosis

Cdk inhibitory proteins (CKIs)

Sic1 (budding yeast)

suppresses Cdk activity in G₁; phosphorylation by Cdk1 triggers its destruction

p27 (mammals)

suppresses G₁/S-Cdk and S-Cdk activities in G₁; helps cells to withdraw from cell cycle

when they terminally differentiate; phosphorylation by Cdk2 triggers its ubiquitylation by SCF

p21 (mammals)

suppresses G₁/S-Cdk and S-Cdk activities

following DNA damage in G₁; transcriptionally activated by p53

p16 (mammals)

suppresses G₁-Cdk activity in G₁; frequently inactivated in cancer

Ubiquitin ligases and their activators

SCF	catalyzes ubiquitylation of regulatory proteins involved in G ₁ control, including CKIs (Sic1 in budding yeast, p27 in mammals); phosphorylation of target protein usually required for this activity
APC	catalyzes ubiquitylation of regulatory proteins involved primarily in exit from mitosis, including Securin and M-cyclins; regulated by association with activating subunits
Cdc20	APC-activating subunit in all cells; triggers initial activation of APC at metaphase-to-anaphase transition; stimulated by M-Cdk activity
Hct1	maintains APC activity after anaphase and throughout G ₁ ; inhibited by Cdk activity

Gene regulatory proteins

E2F	promotes transcription of genes required for G ₁ /S progression, including genes encoding G ₁ /S cyclins, S-cyclins, and proteins required for DNA synthesis; stimulated when G ₁ -Cdk phosphorylates Rb in response to extracellular mitogens
p53	promotes transcription of genes that induce cell cycle arrest (especially p21) or apoptosis in response to DNA damage or other cell stress; regulated by association with Mdm2, which promotes p53 degradation

Molecular Biology of the Cell → IV. Internal Organization of the Cell → 17. The Cell Cycle and Programmed Cell Death

Programmed Cell Death (Apoptosis)

The cells of a multicellular organism are members of a highly organized community. The number of cells in this community is tightly regulated—not simply by controlling the rate of cell division, but also by controlling the rate of cell death. If cells are no longer needed, they commit suicide by activating an intracellular death program. This process is therefore called **programmed cell death**, although it is more commonly called apoptosis (from a Greek word meaning "falling off," as leaves from a tree).

The amount of apoptosis that occurs in developing and adult animal tissues can be astonishing. In the developing vertebrate nervous system, for example, up to half or more of the nerve cells normally die soon after they are formed. In a healthy adult human, billions of cells die in the bone marrow and intestine every hour. It seems remarkably wasteful for so many cells to die, especially as the vast majority are perfectly healthy at the time they kill themselves. What purposes does this massive cell death serve?

In some cases, the answers are clear. Mouse paws, for example, are sculpted by cell death during embryonic development: they start out as spadelike structures, and the individual digits separate only as the cells between them die (Figure 17-35). In other cases, cells die when the structure they form is no longer needed. When a tadpole changes into a frog, the cells in the tail die, and the tail, which is not needed in the frog, disappears (Figure 17-36). In many other cases, cell death helps regulate cell numbers. In the developing nervous system, for example, cell death adjusts the number of nerve cells to match the number of target cells that require innervation. In all these cases, the cells die by apoptosis.

In adult tissues, cell death exactly balances cell division. If this were not so, the tissue would grow or shrink. If part of the liver is removed in an adult rat, for example, liver cell proliferation increases to make up the loss. Conversely, if a rat is treated with the drug phenobarbital—which stimulates liver cell division (and thereby liver enlargement)—and then the phenobarbital treatment is stopped, apoptosis in the liver greatly increases until the liver has returned to its original size, usually within a week or so. Thus, the liver is kept

at a constant size through the regulation of both the cell death rate and the cell birth rate.

In this short section, we describe the molecular mechanisms of apoptosis and its control. In the final section, we consider how the extracellular control of cell proliferation and cell death contributes to the regulation of cell numbers in multicellular organisms.

Apoptosis Is Mediated by an Intracellular Proteolytic Cascade

Cells that die as a result of acute injury typically swell and burst. They spill their contents all over their neighbors—a process called *cell necrosis*—causing a potentially damaging inflammatory response. By contrast, a cell that undergoes apoptosis dies neatly, without damaging its neighbors. The cell shrinks and condenses. The cytoskeleton collapses, the nuclear envelope disassembles, and the nuclear DNA breaks up into fragments. Most importantly, the cell surface is altered, displaying properties that cause the dying cell to be rapidly phagocytosed, either by a neighboring cell or by a macrophage (a specialized phagocytic cell, discussed in [Chapter 24](#)), before any leakage of its contents occurs ([Figure 17-37](#)). This not only avoids the damaging consequences of cell necrosis but also allows the organic components of the dead cell to be recycled by the cell that ingests it.

The intracellular machinery responsible for apoptosis seems to be similar in all animal cells. This machinery depends on a family of proteases that have a cysteine at their active site and cleave their target proteins at specific aspartic acids. They are therefore called caspases. Caspases are synthesized in the cell as inactive precursors, or *procaspases*, which are usually activated by cleavage at aspartic acids by other caspases ([Figure 17-38A](#)). Once activated, caspases cleave, and thereby activate, other procaspases, resulting in an amplifying proteolytic cascade ([Figure 17-38B](#)). Some of the activated caspases then cleave other key proteins in the cell. Some cleave the nuclear lamins, for example, causing the irreversible breakdown of the nuclear lamina; another cleaves a protein that normally holds a DNA-degrading enzyme (a DNase) in an inactive form, freeing the DNase to cut up the DNA in the cell nucleus. In this way, the cell dismantles itself quickly and neatly, and its corpse is rapidly taken up and digested by another cell.

Activation of the intracellular cell death pathway, like entry into a new stage of the cell cycle, is usually triggered in a complete, all-or-none fashion. The protease cascade is not only destructive and self-amplifying but also irreversible, so that once a cell reaches a critical point along the path to destruction, it cannot turn back. [↑ TOP](#)

Procaspases Are Activated by Binding to Adaptor Proteins

All nucleated animal cells contain the seeds of their own destruction, in the form of various inactive procaspases that lie waiting for a signal to destroy the cell. It is therefore not surprising that caspase activity is tightly regulated inside the cell to ensure that the death program is held in check until needed.

How are procaspases activated to initiate the caspase cascade? A general principle is that the activation is triggered by adaptor proteins that bring multiple copies of specific procaspases, known as *initiator procaspases*, close together in a complex or aggregate. In some cases, the initiator procaspases have a small amount of protease activity, and forcing them together into a complex causes them to cleave each other, triggering their mutual activation. In other cases, the aggregation is thought to cause a conformational change that activates the procaspase. Within moments, the activated caspase at the top of the cascade cleaves downstream procaspases to amplify the death signal and spread it throughout the cell (see Figure 17-38B).

Procaspase activation can be triggered from outside the cell by the activation of *death receptors* on the cell surface. Killer lymphocytes (discussed in Chapter 24), for example, can induce apoptosis by producing a protein called **Fas ligand**, which binds to the death receptor protein **Fas** on the surface of the target cell. The clustered Fas proteins then recruit intracellular adaptor proteins that bind and aggregate procaspase-8 molecules, which cleave and activate one another. The activated caspase-8 molecules then activate downstream procaspases to induce apoptosis (Figure 17-39A). Some stressed or damaged cells kill themselves by producing both the Fas ligand and the Fas protein, thereby triggering an intracellular caspase cascade.

When cells are damaged or stressed, they can also kill themselves by triggering procaspase aggregation and activation from within the cell. In the best understood pathway, mitochondria are induced to release the electron carrier protein *cytochrome c* (see Figure 14-26) into the cytosol, where it binds and activates an adaptor protein called **Apaf-1** (Figure 17-39B). This mitochondrial pathway of procaspase activation is recruited in most forms of apoptosis to initiate or to accelerate and amplify the caspase cascade. DNA damage, for example, as discussed earlier, can trigger apoptosis. This response usually requires p53, which can activate the transcription of genes that encode proteins that promote the release of cytochrome *c* from mitochondria. These proteins belong to the Bcl-2 family.  [TOP](#)

Bcl-2 Family Proteins and IAP Proteins Are the Main Intracellular Regulators of the Cell Death Program

The **Bcl-2 family** of intracellular proteins helps regulate the activation of procaspases. Some members of this family, like *Bcl-2* itself or *Bcl-X_L*, inhibit apoptosis, at least partly by blocking the release of cytochrome *c* from

mitochondria. Other members of the Bcl-2 family are not death inhibitors, but instead promote procaspase activation and cell death. Some of these apoptosis promoters, such as *Bad*, function by binding to and inactivating the death-inhibiting members of the family, whereas others, like *Bax* and *Bak*, stimulate the release of cytochrome *c* from mitochondria. If the genes encoding Bax and Bak are both inactivated, cells are remarkably resistant to most apoptosis-inducing stimuli, indicating the crucial importance of these proteins in apoptosis induction. Bax and Bak are themselves activated by other apoptosis-promoting members of the Bcl-2 family such as Bid.

Another important family of intracellular apoptosis regulators is the **IAP (inhibitor of apoptosis) family**. These proteins are thought to inhibit apoptosis in two ways: they bind to some procaspases to prevent their activation, and they bind to caspases to inhibit their activity. IAP proteins were originally discovered as proteins produced by certain insect viruses, which use them to prevent the infected cell from killing itself before the virus has had time to replicate. When mitochondria release cytochrome *c* to activate Apaf-1, they also release a protein that blocks IAPs, thereby greatly increasing the efficiency of the death activation process.

The intracellular cell death program is also regulated by extracellular signals, which can either activate apoptosis or inhibit it. These signal molecules mainly act by regulating the levels or activity of members of the Bcl-2 and IAP families. We see in the next section how these signal molecules help multicellular organisms regulate their cell numbers. [↑ TOP](#)

Summary

In multicellular organisms, cells that are no longer needed or are a threat to the organism are destroyed by a tightly regulated cell suicide process known as programmed cell death, or apoptosis. Apoptosis is mediated by proteolytic enzymes called caspases, which trigger cell death by cleaving specific proteins in the cytoplasm and nucleus. Caspases exist in all cells as inactive precursors, or procaspases, which are usually activated by cleavage by other caspases, producing a proteolytic caspase cascade. The activation process is initiated by either extracellular or intracellular death signals, which cause intracellular adaptor molecules to aggregate and activate procaspases. Caspase activation is regulated by members of the Bcl-2 and IAP protein families. [↑ TOP](#)

procaspase molecules. In this way, an initial activation of a small number of procaspase molecules (called initiator caspases) can lead, via an amplifying chain reaction (a cascade), to the explosive activation of a large number of procaspase molecules. Some of the activated caspases (called effector caspases) then cleave a number of key proteins in the cell, including specific cytosolic proteins and nuclear lamins, leading to the controlled death of the cell.

Extracellular Control of Cell Division, Cell Growth, and Apoptosis

A fertilized mouse egg and a fertilized human egg are similar in size, yet they produce animals of very different sizes. What factors in the control of cell behavior in humans and mice are responsible for these size differences? The same fundamental question can be asked for each organ and tissue in an animal's body. What factors in the control of cell behavior explain the length of an elephant's trunk or the size of its brain or its liver? These questions are largely unanswered, at least in part because they have received relatively little attention compared with other questions in cell and developmental biology. It is nevertheless possible to say what the ingredients of an answer must be.

The size of an organ or organism depends mainly on its total cell mass, which depends on both the total number of cells and the size of the cells. Cell number, in turn, depends on the amounts of cell division and cell death. Organ and body size are therefore determined by three fundamental processes: cell growth, cell division, and cell death. Each is independently regulated—both by intracellular programs and by extracellular signal molecules that control these programs.

The extracellular signal molecules that regulate cell size and cell number are generally either soluble secreted proteins, proteins bound to the surface of cells, or components of the extracellular matrix. The factors that promote organ or organism growth can be operationally divided into three major classes:

1. *Mitogens*, which stimulate cell division, primarily by relieving intracellular negative controls that otherwise block progress through the cell cycle.
2. *Growth factors*, which stimulate cell growth (an increase in cell mass) by promoting the synthesis of proteins and other macromolecules and by inhibiting their degradation.
3. *Survival factors*, which promote cell survival by suppressing apoptosis.

Some extracellular signal molecules promote all of these processes, while

others promote one or two of them. Indeed, the term *growth factor* is often used inappropriately to describe a factor that has any of these activities. Even worse, the term *cell growth* is often used to mean an increase in cell number, or *cell proliferation*.

In this section, we first discuss how these extracellular signals stimulate cell division, cell growth, and cell survival, thereby promoting the growth of an animal and its organs. We then consider how other extracellular signals can act in the opposite way, to inhibit cell growth or cell division or to stimulate apoptosis, thereby inhibiting organ growth.

Mitogens Stimulate Cell Division

Unicellular organisms tend to grow and divide as fast as they can, and their rate of proliferation depends largely on the availability of nutrients in the environment. The cells of a multicellular organism, however, divide only when more cells are needed by the organism. Thus, for an animal cell to proliferate, nutrients are not enough. It must also receive stimulatory extracellular signals, in the form of mitogens, from other cells, usually its neighbors. Mitogens act to overcome intracellular braking mechanisms that block progress through the cell cycle.

One of the first mitogens to be identified was **platelet-derived growth factor (PDGF)**, and it is typical of many others discovered since. The path to its isolation began with the observation that fibroblasts in a culture dish proliferate when provided with *serum* but not when provided with *plasma*. Plasma is prepared by removing the cells from blood without allowing clotting to occur; serum is prepared by allowing blood to clot and taking the cell-free liquid that remains. When blood clots, platelets incorporated in the clot are triggered to release the contents of their secretory vesicles (Figure 17-40). The superior ability of serum to support cell proliferation suggested that platelets contain one or more mitogens. This hypothesis was confirmed by showing that extracts of platelets could serve instead of serum to stimulate fibroblast proliferation. The crucial factor in the extracts was shown to be a protein, which was subsequently purified and named PDGF. In the body, PDGF liberated from blood clots probably has a major role in stimulating cell division during wound healing.

PDGF is only one of over 50 proteins that are known to act as mitogens. Most of these proteins are broad-specificity factors, like PDGF and *epidermal growth factor (EGF)*, that can stimulate many types of cells to divide. Thus, PDGF acts on a range of cell types, including fibroblasts, smooth muscle cells, and neuroglial cells. Similarly, EGF acts not only on epidermal cells but also on many other cell types, including both epithelial and nonepithelial cells. At the opposite extreme lie narrow-specificity factors such as *erythropoietin*, which induces the proliferation of red blood cell precursors only.

In addition to mitogens that stimulate cell division, there are factors, such as some members of the *transforming growth factor- β* (*TGF- β*) family, that act on some cells to stimulate cell proliferation and others to inhibit it, or that stimulate at one concentration and inhibit at another. Indeed, like PDGF, many mitogens have other actions beside the stimulation of cell division: they can stimulate cell growth, survival, differentiation, or migration, depending on the circumstances and the cell type. [↑ TOP](#)

Cells Can Delay Division by Entering a Specialized Nondividing State

In the absence of a mitogenic signal to proliferate, Cdk inhibition in G_1 is maintained, and the cell cycle arrests. In some cases, cells partly disassemble their cell-cycle control system and exit from the cycle to a specialized, nondividing state called G_0 .

Most cells in our body are in G_0 , but the molecular basis and reversibility of this state vary in different cell types. Neurons and skeletal muscle cells, for example, are in a *terminally differentiated* G_0 state, in which their cell-cycle control system is completely dismantled: the expression of the genes encoding various Cdks and cyclins are permanently turned off, and cell division never occurs. Other cell types withdraw from the cell cycle only transiently and retain the ability to reassemble the cell-cycle control system quickly and reenter the cycle. Most liver cells, for example, are in G_0 , but they can be stimulated to divide if the liver is damaged. Still other types of cells, including some lymphocytes, withdraw from and re-enter the cell cycle repeatedly throughout their lifetime.

Almost all the variation in cell-cycle length in the adult body occurs during the time the cell spends in G_1 or G_0 . By contrast, the time taken for a cell to progress from the beginning of S phase through mitosis is usually brief (typically 12–24 hours in mammals) and relatively constant, regardless of the interval from one division to the next. [↑ TOP](#)

Mitogens Stimulate G_1 -Cdk and G_1 /S-Cdk Activities

For the vast majority of animal cells, mitogens control the rate of cell division by acting in the G_1 phase of the cell cycle. As discussed earlier, multiple mechanisms act during G_1 to suppress Cdk activity and thereby hinder entry into S phase. Mitogens act to release the brakes on Cdk activity, thereby allowing S phase to begin. They do so by binding to cell-surface receptors to initiate a complex array of intracellular signals that penetrate deep into the cytoplasm and nucleus (discussed in [Chapter 15](#)). The ultimate result is the

activation of G₁-Cdk and G₁/S-Cdk complexes, which overcome the inhibitory barriers that normally block progression into S phase.

As we discuss in [Chapter 15](#), an early step in mitogen signaling is often the activation of the small GTPase **Ras**, which leads to the activation of a *MAP kinase cascade*. By uncertain mechanisms, this leads to increased levels of the gene regulatory protein **Myc**. Myc promotes cell-cycle entry by several overlapping mechanisms ([Figure 17-41](#)). It increases the transcription of genes that encode G₁ cyclins (D cyclins), thereby increasing G₁-Cdk (cyclin D-Cdk4) activity. In addition, Myc increases the transcription of a gene that encodes a component of the SCF ubiquitin ligase. This mechanism promotes the degradation of the CKI protein p27, leading to increased G₁/S-Cdk (cyclin E-Cdk2) activity. As discussed earlier, increased G₁-Cdk and G₁/S-Cdk activities stimulate phosphorylation of the inhibitory protein Rb, which then leads to activation of the gene regulatory protein E2F. Myc may also stimulate the transcription of the gene encoding E2F, further promoting E2F activity in the cell. The end result is the increased transcription of genes required for entry into S phase (see [Figure 17-30](#)). As we discuss later, Myc also has a major role in stimulating the transcription of genes that increase cell growth. [↑ TOP](#)

Abnormal Proliferation Signals Cause Cell-Cycle Arrest or Cell Death

As we discuss in [Chapter 23](#), many of the components of intracellular signaling pathways are encoded by genes that were originally identified as cancer-promoting genes, or *oncogenes*, because mutations in them contribute to the development of cancer. The mutation of a single amino acid in Ras, for example, causes the protein to become permanently overactive, leading to constant stimulation of Ras-dependent signaling pathways, even in the absence of mitogenic stimulation. Similarly, mutations that cause an overexpression of Myc promote excessive cell growth and proliferation and thereby promote the development of cancer.

Surprisingly, however, when Ras or Myc is experimentally hyperactivated in most normal cells, the result is not excessive proliferation but the opposite: the activation of checkpoint mechanisms causes the cells to undergo either cell-cycle arrest or apoptosis. The normal cell seems able to detect abnormal mitogenic stimulation, and it responds by preventing further division. Such checkpoint responses help prevent the survival and proliferation of cells with various cancer-promoting mutations.

Although it is not known how a cell detects excessive mitogenic stimulation, such stimulation often leads to the production of a cell-cycle inhibitor protein called **p19^{ARF}**, which binds and inhibits Mdm2. As discussed earlier, Mdm2

normally promotes p53 degradation. Activation of p19^{ARF} therefore causes p53 levels to increase, thereby inducing either cell-cycle arrest or apoptosis ([Figure 17-42](#)).

How do cancer cells ever arise if these mechanisms block the division or survival of mutant cells with overactive proliferation signals? The answer is that the protective system is often inactivated in cancer cells by mutations in the genes that encode essential components of the checkpoint responses, such as p19^{ARF} or p53. [↑ TOP](#)

Human Cells Have a Built-in Limitation on the Number of Times They Can Divide

Cell division is controlled not only by extracellular mitogens but also by intracellular mechanisms that can limit cell proliferation. Many animal precursor cells, for example, divide a limited number of times before they stop and terminally differentiate into permanently arrested, specialized cells. Although the stopping mechanisms are poorly understood, a progressive increase in CKI proteins probably contributes in some cases. Mice that are deficient in the CKI p27, for example, have more cells than normal in all of their organs because the stopping mechanisms are apparently defective.

The best-understood intracellular mechanism that limits cell proliferation occurs in human fibroblasts. Fibroblasts taken from a normal human tissue go through only about 25–50 population doublings when cultured in a standard mitogenic medium. Toward the end of this time, proliferation slows down and finally halts, and the cells enter a nondividing state from which they never recover. This phenomenon is called replicative cell senescence, although it is unlikely to be responsible for the senescence (aging) of the organism. Organism senescence is thought to depend, in part at least, on progressive oxidative damage to macromolecules, in as much as strategies that reduce metabolism (such as reduced food intake), and thereby reduce the production of reactive oxygen species, can extend the lifespan of experimental animals.

Replicative cell senescence in human fibroblasts seems to be caused by changes in the structure of the telomeres, the repetitive DNA sequences and associated proteins at the ends of chromosomes. As discussed in [Chapter 5](#), when a cell divides, telomeric DNA sequences are not replicated in the same manner as the rest of the genome but instead are synthesized by the enzyme telomerase. By mechanisms that remain unclear, telomerase also promotes the formation of protein cap structures that protect the chromosome ends. Because human fibroblasts, and many other human somatic cells, are deficient in telomerase, their telomeres become shorter with every cell division, and their protective protein caps progressively deteriorate. Eventually, DNA damage occurs at chromosome ends. The damage activates a p53-dependent cell-cycle arrest that resembles the arrest caused by other types of DNA damage (see

Figure 17-33).

The lack of telomerase in most somatic cells has been proposed to help protect humans from the potentially damaging effects of runaway cell proliferation, as occurs in cancer. Unfortunately, most cancer cells have regained the ability to produce telomerase and therefore maintain telomere function as they proliferate; as a result, they do not undergo replicative cell senescence (discussed in Chapter 23). The forced expression of telomerase in normal human fibroblasts, using genetic engineering techniques, has the same effect (Figure 17-43).

Normal rodent cells, by contrast, usually maintain telomerase activity and telomere function as they proliferate and therefore do not undergo this type of replicative senescence. When overstimulated to proliferate in culture, however, they frequently activate the p19^{ARF}-dependent checkpoint mechanism described earlier and eventually stop dividing. Mutations that inactivate these checkpoints make it easier for rodent cells to proliferate indefinitely in culture. Such mutant cells are often described as "immortalized". If cultured in optimal conditions that avoid the activation of checkpoint responses, however, at least some normal rodent cells also seem able to proliferate indefinitely. Nevertheless, rodents age much more rapidly than humans. [↑ TOP](#)

Extracellular Growth Factors Stimulate Cell Growth

The growth of an organism or organ depends on cell growth: cell division alone cannot increase total cell mass without cell growth. In single-celled organisms such as yeasts, cell growth (like cell division) requires only nutrients. In animals, by contrast, cell growth and cell division both depend on signals from other cells.

The extracellular growth factors that stimulate cell growth bind to receptors on the cell surface and activate intracellular signaling pathways. These pathways stimulate the accumulation of proteins and other macromolecules, and they do so by both increasing their rate of synthesis and decreasing their rate of degradation.

One of the most important intracellular signaling pathways activated by growth factor receptors involves the enzyme **PI 3-kinase**, which adds a phosphate from ATP to the 3 position of inositol phospholipids in the plasma membrane. As discussed in Chapter 15, the activation of PI 3-kinase leads to the activation of several protein kinases, including **S6 kinase**. The S6 kinase phosphorylates ribosomal protein S6, increasing the ability of ribosomes to translate a subset of mRNAs, most of which encode ribosomal components. Protein synthesis therefore increases. When the gene encoding S6 kinase is inactivated in *Drosophila*, the mutant flies are small; whereas cell numbers are normal, cell size is abnormally small. Growth factors also activate a translation initiation factor called *eIF4E*, further increasing protein synthesis and cell

growth ([Figure 17-44](#)).

Growth factor stimulation also leads to increased production of the gene regulatory protein Myc, which also plays an important part in signaling by mitogens (see [Figure 17-41](#)). Myc increases the transcription of a number of genes that encode proteins involved in cell metabolism and macromolecular synthesis. In this way, it stimulates both cell metabolism and cell growth.

Some extracellular signal proteins, including PDGF, can act as both growth factors and mitogens, stimulating both cell growth and cell-cycle progression. This functional overlap is achieved in part by overlaps in the intracellular signaling pathways that control these two processes. The signaling protein Ras, for example, is activated by both growth factors and mitogens. It can stimulate the PI3-kinase pathway to promote cell growth and the MAP-kinase pathway to trigger cell-cycle progression. Similarly, as described above, Myc stimulates both cell growth and cell-cycle progression. Extracellular factors that act as both growth factors and mitogens help ensure that cells maintain their appropriate size as they proliferate.

Cell growth and division, however, can be controlled by separate extracellular signal proteins in some cell types. Such independent control may be particularly important during embryonic development, when dramatic changes in the size of certain cell types can occur. Even in adult animals, however, growth factors can stimulate cell growth without affecting cell division. The size of a sympathetic neuron, for example, which has permanently withdrawn from the cell cycle, depends on the amount of **nerve growth factor (NGF)** secreted by the target cells it innervates. The greater the amount of NGF the neuron has access to, the larger it becomes. It remains a mystery, however, how different cell types in the same animal grow to be so different in size ([Figure 17-45](#)). [↑ TOP](#)

Extracellular Survival Factors Suppress Apoptosis

Animal cells need signals from other cells—not only to grow and proliferate, but also to survive. If deprived of such survival factors, cells activate their intracellular death program and die by apoptosis. This arrangement ensures that cells survive only when and where they are needed. Nerve cells, for example, are produced in excess in the developing nervous system and then compete for limited amounts of survival factors that are secreted by the target cells they contact. Nerve cells that receive enough survival factor live, while the others die by apoptosis ([Figure 17-46](#)). A similar dependence on survival signals from neighboring cells is thought to control cell numbers in other tissues, both during development and in adulthood.

Survival factors, just like mitogens and growth factors, usually bind to cell-surface receptors. Binding activates signaling pathways that keep the death program suppressed, often by regulating members of the Bcl-2 family of

proteins. Some factors, for example, stimulate the increased production of apoptosis-suppressing members of this family. Others act by inhibiting the function of apoptosis-promoting members of the family ([Figure 17-47A](#)). In *Drosophila*, and probably in vertebrates as well, some survival factors also act by stimulating the activity of IAPs, which suppress apoptosis ([Figure 17-47B](#)). [↑ TOP](#)

Neighboring Cells Compete for Extracellular Signal Proteins

When most types of mammalian cells are cultured in a dish in the presence of serum, they adhere to the bottom of the dish, spread out, and divide until a confluent monolayer is formed. Each cell is attached to the dish and contacts its neighbors on all sides. At this point, normal cells, unlike cancer cells, stop proliferating—a phenomenon known as *density-dependent inhibition of cell division*. This phenomenon was originally described in terms of "contact inhibition" of cell division, but it is unlikely that cell-cell contact interactions are solely responsible. The cell population density at which cell proliferation ceases in the confluent monolayer increases with increasing concentration of serum in the medium. Moreover, passing a stream of fresh culture medium over a confluent layer of fibroblasts reduces the diffusional limitation to the supply of mitogens, and it induces the cells under the stream of medium to divide at densities at which they would normally be inhibited from doing so ([Figure 17-48](#)). Thus, density-dependent inhibition of cell proliferation seems to reflect, in part at least, the ability of a cell to deplete the medium locally of extracellular mitogens, thereby depriving its neighbors.

This type of competition could be important for cells in tissues as well as in culture, because it prevents them from proliferating beyond a certain population density, determined by the available amounts of mitogens, growth factors, and survival factors. The amounts of these factors in tissues is usually limited, and increasing their amounts results in an increase in cell number, cell size, or both. Thus, the concentrations of these factors in tissues have important roles in determining cell size and number. [↑ TOP](#)

Many Types of Normal Animal Cells Need Anchorage to Grow and Proliferate

The shape of a cell changes as it spreads and crawls out over a substratum to occupy vacant space, and this can have a major impact on cell growth, cell division, and cell survival. When normal fibroblasts or epithelial cells, for example, are cultured in suspension, unattached to any solid surface and therefore rounded up, they almost never divide—a phenomenon known as *anchorage dependence* of cell division ([Figure 17-49](#)). But when these cells are allowed to settle and adhere to a sticky substrate, they rapidly form focal adhesions at sites of attachment, and then begin to grow and proliferate.

How are the growth and proliferation signals generated by cell attachments? *Focal adhesions* are places where extracellular matrix molecules, such as laminin or fibronectin, interact with cell-surface matrix receptors called *integrins*, which are linked to the actin cytoskeleton (discussed in [Chapter 19](#)). The binding of extracellular matrix molecules to integrins leads to the local activation of protein kinases, including *focal adhesion kinase (FAK)*, which in turn leads to the activation of intracellular signaling pathways that can promote the survival, growth, and division of cells ([Figure 17-50](#)).

Like other controls on cell division, anchorage control operates in G_1 . Cells require anchorage to progress through G_1 into S phase, but anchorage is not required for completing the cycle. In fact, cells commonly loosen their attachments and round up as they pass through M phase. This cycle of attachment and detachment presumably allows cells in tissues to rearrange their contacts with other cells and with the extracellular matrix. In this way, tissues can accommodate the daughter cells produced by cell division and then bind them securely into the tissue before they are allowed to begin the next division cycle. [↑ TOP](#)

Some Extracellular Signal Proteins Inhibit Cell Growth, Cell Division, and Survival

The extracellular signal proteins discussed in this chapter—mitogens, growth factors and survival factors—are positive regulators of cell-cycle progression, cell growth, and cell survival, respectively. They therefore tend to increase the size of organs and organisms. In some tissues, however, cell and tissue size also is influenced by inhibitory extracellular signal proteins that oppose the positive regulators and thereby inhibit organ growth.

The best-understood inhibitory signal proteins are TGF- β and its relatives. TGF- β inhibits the proliferation of several cell types, either by blocking cell-cycle progression in G_1 or by stimulating apoptosis. As discussed in [Chapter 15](#), TGF- β binds to cell-surface receptors and initiates an intracellular signaling pathway that leads to changes in the activities of gene regulatory proteins called Smads. This results in complex and poorly understood changes in the transcription of genes encoding regulators of cell division and cell death.

One example of an apoptosis-inducing extracellular signal is *bone morphogenetic protein (BMP)*, a TGF- β family member. BMP helps trigger the apoptosis that removes the tissue between the developing digits in the mouse paw (see [Figure 17-35](#)). Like TGF- β , BMP stimulates changes in the transcription of genes that regulate cell death, although the nature of these genes remains unclear.

The overall size of an organ may be limited in some cases by inhibitory

signaling proteins. *Myostatin*, for example, is a TGF- β family member that normally inhibits the proliferation of myoblasts that fuse to form skeletal muscle cells. When the gene that encodes myostatin is deleted in mice, muscles grow to be several times larger than normal (see [Figure 22-43](#)). Both the number and the size of muscle cells increase. Remarkably, two breeds of cattle that were bred for large muscles have both turned out to have mutations in the gene encoding myostatin ([Figure 17-51](#)). [↑ TOP](#)

Intricately Regulated Patterns of Cell Division Generate and Maintain Body Form

The life of multicellular organisms begins with a series of division cycles that are controlled according to intricate rules. This is strikingly illustrated by the nematode *Caenorhabditis elegans*. The fertilized egg of *C. elegans* divides to produce an adult worm with precisely 959 somatic cell nuclei (in the male), each of which is generated by its own characteristic and absolutely predictable sequence of cell divisions. (The initial cell number is greater than this, but more than 100 cells die by apoptosis during development.) In general, the controls that generate such precise cell numbers do not operate by merely counting cell divisions according to a clocklike schedule. Instead, the organism seems mainly to control total cell mass, which depends not only on cell numbers but also on cell size. Salamanders of different ploidies, for example, are the same size but have different numbers of cells. Individual cells in a pentaploid salamander are about five times the volume of those in a haploid salamander, and in each organ the pentaploids have generated only one-fifth as many cells as their haploid cousins, so that the organs are about the same size in the two animals ([Figures 17-52](#) and [17-53](#)). Evidently, in this case (and in many others) the size of organs and organisms depends on mechanisms that can somehow measure total cell mass.

The development of limbs and organs of specific size and shape depends on complex positional controls, as well as on local concentrations of extracellular signal proteins that stimulate or inhibit cell growth, division, and survival. As we discuss in [Chapter 21](#), some of the genes that help pattern these processes in the embryo are now known. A great deal remains to be learned, however, about how these genes regulate cell growth, division, survival, and differentiation to generate a complex organism (discussed in [Chapter 21](#)).

The controls that govern these processes in an adult body are also poorly understood. When a skin wound heals in a vertebrate, for example, about a dozen cell types, ranging from fibroblasts to Schwann cells, must be regenerated in appropriate numbers and in appropriate positions to reconstruct the lost tissue. The mechanisms that control cell proliferation in tissues are likewise central to the understanding of cancer, a disease in which the controls go wrong, as discussed in [Chapter 23](#). [↑ TOP](#)

Summary

In multicellular animals, cell size, cell division, and cell death are carefully controlled to ensure that the organism and its organs achieve and maintain an appropriate size. Three classes of extracellular signal proteins contribute to this control, although many of them affect two or more of these processes. Mitogens stimulate the rate of cell division by removing intracellular molecular brakes that restrain cell-cycle progression in G_1 . Growth factors promote an increase in cell mass by stimulating the synthesis and inhibiting the degradation of macromolecules. Survival factors increase cell numbers by inhibiting apoptosis. Extracellular signals that inhibit cell division or cell growth, or induce cells to undergo apoptosis, also contribute to size control. [↑ TOP](#)

Figure 17-40. A platelet. Platelets are miniature cells without a nucleus. They circulate in the blood and help stimulate blood clotting at sites of tissue damage, thereby preventing excessive bleeding. They also release various factors that stimulate healing. The platelet shown here has been cut in half to show its secretory vesicles, some of which contain platelet-derived growth factor (PDGF). See also [Figure 16-47B-D](#).

Figure 17-41. A simplified model of one way that mitogens stimulate cell division. The binding of mitogens to cell-surface receptors leads to the activation of Ras and a MAP kinase cascade. One effect of this pathway is the increased production of the gene regulatory protein Myc. Myc increases the transcription of several genes, including the gene encoding cyclin D and a gene encoding a subunit of the SCF ubiquitin ligase. The resulting increase in G_1 -Cdk and G_1/S -Cdk activities promotes Rb phosphorylation and activation of the gene regulatory protein E2F, resulting in S-phase entry (see [Figure 17-30](#)). Myc may also promote E2F activity directly by stimulating the transcription of the *E2F* gene. Although, for simplicity, Myc is shown as a monomer, it functions as a heterodimer with another protein called Max.

Figure 17-42. Cell-cycle arrest or apoptosis induced by excessive stimulation of mitogenic pathways. Abnormally high levels of Myc cause the activation of p19^{ARF}, which binds and inhibits Mdm2 and thereby causes increased p53 levels (see Figure 17-33). Depending on the cell type and extracellular conditions, p53 then causes either cell-cycle arrest or apoptosis.

Figure 17-43. Overcoming replicative cell senescence by the forced expression of telomerase. (A) Normal human fibroblasts do not contain telomerase, and so their telomeres gradually shorten and lose their normal cap structure as the cells proliferate. Cells forced to express telomerase, however, maintain telomere length (and normal cap structures) after many divisions. (B) The normal human fibroblasts stopped dividing after about 50–60 divisions in these experiments, whereas the cells expressing telomerase were still dividing at the end of the experiment. (Based on A. Bodnar et al., *Science* 279:349–352, 1998.)

Figure 17-44. One way in which growth factors promote cell growth. In this simplified scheme, activation of cell-surface receptors leads to the activation of PI 3-kinase, which promotes protein synthesis, at least partly through the activation of eIF4E and S6 kinase. Growth factors also inhibit protein breakdown (not shown) by poorly understood pathways.

The size difference between a neuron (from the retina) and a lymphocyte in a mammal.

Figure 17-45. The size difference between a neuron (from the retina) and a lymphocyte in a mammal. Both cells contain the same amount of DNA. A neuron grows progressively larger after it has permanently withdrawn from the cell cycle. During this time, the ratio of cytoplasm to DNA increases enormously (by a factor of more than 10^5 for some neurons). (Neuron from B. B. Boycott, in *Essays on the Nervous System* [R. Bellairs and E.G. Gray, eds]. Oxford, UK: Clarendon Press, 1974.)

Figure 17-46. The function of cell death in matching the number of developing nerve cells to the number of target cells they contact. More nerve cells are produced than can be supported by the limited amount of survival factors released by the target cells. Therefore, some cells receive an insufficient amount of survival factors to keep their suicide program suppressed and, as a consequence, undergo apoptosis. This strategy of overproduction followed by culling ensures that all target cells are contacted by nerve cells and that the extra nerve cells are automatically eliminated.

Figure 17-47. Two ways in which survival factors suppress apoptosis. (A) In mammalian cells, the binding of some survival factors to cell-surface receptors leads to the activation of various protein kinases, including protein kinase B (PKB), that phosphorylate and inactivate the Bcl-2 family member Bad. When not phosphorylated, Bad promotes apoptosis by binding and inhibiting Bcl-2. Once phosphorylated, Bad dissociates, freeing Bcl-2 to suppress apoptosis. As indicated, PKB also suppresses death by phosphorylating and thereby inhibiting gene regulatory proteins of the Forkhead family that stimulate the transcription of genes that encode proteins that promote apoptosis. (B) In *Drosophila*, some survival factors inhibit apoptosis by stimulating the phosphorylation of the Hid protein. When not phosphorylated, Hid promotes cell death by inhibiting IAPs. Once phosphorylated, Hid no longer inhibits IAPs, which become active and block cell death.

Figure 17-49. The dependence of cell division on cell shape and anchorage. In this experiment, cells are either held in suspension or allowed to settle on patches of an adhesive material (palladium) on a nonadhesive substratum. The patch diameter, which is variable, determines the extent to which an individual cell spreads and the probability that it will progress into S phase. ^3H -thymidine is added to the culture medium, and after 1 or 2 days, the culture is fixed and autoradiographed to determine the percentage of cells that have entered S phase (see Figure 17-11A). (A) Few cells of the 3T3 cell line enter S phase when held rounded up in suspension, but adherence even to a very tiny patch—one that is too small to allow spreading—enables many of them to enter S phase. (B and C) These scanning electron micrographs show a cell perched on a small patch compared with a cell spread on a large patch. In contrast to fibroblasts and epithelial cells, some cell types in the body (including lymphocytes and blood cell precursors) can divide readily in suspension (see also Figure 19-62). (B and C, from C. O'Neill, P. Jordan, and G. Ireland, *Cell* 44:489–496, 1986. ©

Figure 17-50. Focal adhesions as production sites of intracellular signals.

This fluorescence micrograph shows a fibroblast cultured on a substratum coated with the extracellular matrix molecule fibronectin. Actin filaments have been labeled to fluoresce *green*, while activated proteins that contain phosphotyrosine have been labeled with an antibody that is tagged to fluoresce *red*. Where the two components overlap, the resulting color is *orange*. The actin filaments terminate at focal adhesions, where the cell attaches to the substratum. Proteins containing phosphotyrosine are also concentrated at these sites. This is thought to reflect the local activation of focal adhesion kinase (FAK) and other protein kinases stimulated by transmembrane integrin proteins that bind to fibronectin extracellularly and (indirectly) to actin filaments intracellularly. Signals generated at such adhesion sites help regulate cell division, growth, and survival, in both fibroblasts and epithelial cells. (Courtesy of Keith Burridge.)

Figure 17-52. Sections of kidney tubules from salamander larvae of different ploidies. In all organisms, from bacteria to humans, cell size is proportional to ploidy. Pentaploid salamanders, for example, have cells that are much larger than those of haploid salamanders. The animals and their individual organs, however, are the same size because each tissue in the pentaploid animal contains fewer cells. This indicates that the size of an organism or organ is not controlled simply by counting cell divisions or cell numbers; total cell mass must somehow be regulated. (Adapted from G. Fankhauser, in *Analysis of Development* [B.H. Willier, P.A. Weiss, and V. Hamburger, eds.], pp. 126–150. Philadelphia: Saunders, 1955.)

18. The Mechanics of Cell Division

Cells reproduce by duplicating their contents and dividing in two. This cycle of duplication and division, called the cell cycle, is discussed in Chapter 17. In this chapter, we consider the mechanical events of the M phase of the cycle, which is the culmination of the cycle and includes the various stages of nuclear division (*mitosis*) and cytoplasmic division (*cytokinesis*). In a comparatively brief period, the contents of the parent cell, which were doubled during earlier phases of the cycle, are partitioned into two daughter cells. The period between one M phase and the next is called *interphase*, and in most rapidly proliferating cells, it is divided into three phases: *S phase*, in which DNA is replicated (discussed in Chapter 5), and two gap phases, G_1 and G_2 , which provide additional time for the cell to grow (Figure 18-1).

As discussed in detail in Chapter 17, the events of the cell cycle are controlled by the *cell-cycle control system*. The core of the control system consists of various **cyclin-dependent kinases (Cdks)**, which are activated in sequence to trigger various steps of the cycle. The Cdks are activated by the binding of *cyclin* regulatory proteins, as well as by phosphorylation and dephosphorylation of the kinase. They are inactivated by various Cdk inhibitory proteins (CKIs) and by the degradation of the cyclin subunits at specific stages of the cycle.

The **M-phase Cdk (M-Cdk)** triggers a cascade of protein phosphorylation that initiates M phase. These phosphorylations are responsible for the many morphological changes that occur during mitosis in animal cells. The chromosomes condense, the nuclear envelope breaks down, the endoplasmic reticulum and Golgi apparatus reorganize, the cell loosens its adhesions both to other cells and to the extracellular matrix, and the cytoskeleton radically reorganizes to bring about the highly ordered movements that will segregate the replicated chromosomes and divide the cell in two.

Targetted protein degradation by the *anaphase-promoting complex (APC)* (discussed in Chapter 17) has an equally important regulatory role in mitosis. It initiates the separation and segregation of the replicated chromosomes, and it inactivates M-Cdk at the end of mitosis.

We begin this chapter with an overview of M phase. We then discuss mitosis and cytokinesis in turn, focusing mainly on animal cells. We end by considering how M phase may have evolved. We discuss the special features of meiotic cell division in Chapter 20, where we describe the development of germ cells. [↑ TOP](#)

An Overview of M Phase

The central problem for a mitotic cell in M phase is how to accurately separate and distribute (*segregate*) its chromosomes, which were replicated in the preceding S phase, so that each new daughter cell receives an identical copy of the genome (see [Figure 18-1](#)). With minor variations, all eucaryotes solve this problem in a similar way: they assemble specialized cytoskeletal machines—first to pull the duplicated chromosome sets apart and then to split the cytoplasm into two halves. Before the duplicated chromosomes can be separated and distributed equally to the two daughter cells during mitosis, however, they must be appropriately configured, and this process begins in S phase.

Cohesins and Condensins Help Configure Replicated Chromosomes for Segregation

When the chromosomes are duplicated in S phase, the two copies of each replicated chromosome remain tightly bound together as identical **sister chromatids**. The sister chromatids are glued together by multisubunit protein complexes called **cohesins**, which are deposited along the length of each sister chromatid as the DNA is replicated. This cohesion between sister chromatids is crucial to the chromosome segregation process and is broken only late in mitosis (at the start of *anaphase*) to allow the sisters to be pulled apart.

The first readily visible sign that a cell is about to enter M phase is the progressive compaction of the replicated chromosomes, which become visible as threadlike structures—a process called [chromosome condensation](#). In humans, for example, each interphase chromosome becomes compacted after replication into a mitotic chromosome that is about 50 times shorter ([Figure 18-2](#)). As discussed in [Chapter 4](#), proteins called **condensins** do the work of chromosome condensation. Activated M-Cdk phosphorylates some of the condensin subunits, triggering the assembly of condensin complexes on DNA and, thereby, the progressive condensation of the chromosomes. The condensins can use the energy of ATP hydrolysis to promote DNA coiling in a test tube, and they are thought to do the same in cells during chromosome condensation. By a mechanism that is still poorly understood, they eventually

produce fully condensed mitotic chromosomes, with each of the two sister chromatids organized around a linear central axis, where the condensin complexes are concentrated (see [Figure 18-2](#)).

The cohesins and condensins are structurally related, and they work together to configure the replicated chromosomes in preparation for mitosis. Genetic studies show that, if chromatid cohesion is not established properly in S phase, full condensation cannot occur in M phase and chromosomes are abnormally segregated at anaphase. A model for how cohesins can glue two DNA molecules together, while the closely related condensins can bind to a single DNA molecule and induce its supercoiling and condensation, is illustrated in [Figure 18-3](#).

In budding yeast, the sudden degradation and release of the cohesin complexes allows sister chromatids to separate at anaphase. In vertebrate cells, by contrast, most of the cohesin is released from the chromosomes at the start of mitosis, when condensins bind to drive condensation. The small amount of cohesin that remains, however, is enough to hold sister chromatids together until anaphase, when the residual cohesins are degraded, allowing the chromatids to separate, as we discuss later. [↑ TOP](#)

Cytoskeletal Machines Perform Both Mitosis and Cytokinesis

After the chromosomes have condensed, two distinct cytoskeletal machines are assembled in sequence to perform the mechanical processes of mitosis and cytokinesis. Both machines disassemble rapidly after they have completed their tasks.

To produce two genetically identical daughter cells, the cell has to separate its replicated chromosomes and allocate one copy to each daughter cell. In all eucaryotic cells, this task is performed during mitosis by a bipolar *mitotic spindle*, which is composed of microtubules and various proteins that interact with them, including *microtubule-dependent motor proteins* (discussed in [Chapter 16](#)).

Different cytoskeletal structures are responsible for cytokinesis. In animal cells and many unicellular eucaryotes, it is the *contractile ring*; in most plant cells, it is the *phragmoplast*. The contractile ring contains both actin and myosin filaments and forms around the equator of the cell, just under the plasma membrane; as the ring contracts, it pulls the membrane inward, thereby dividing the cell in two ([Figure 18-4](#)). Plant cells, which have a cell wall to contend with, divide their cytoplasm by a very different mechanism. As we discuss later, instead of using a contractile process that acts on the plasma membrane, the phragmoplast constructs a new cell wall from within the cell, between the two sets of replicated chromosomes. [↑ TOP](#)

Two Mechanisms Help Ensure That Mitosis Always Precedes Cytokinesis

In most animal cells, M phase takes only about an hour—a small fraction of the total cell-cycle time, which often lasts 12–24 hours. The rest of the cycle is occupied by interphase. Under the microscope, interphase appears as a deceptively uneventful interlude, in which the cell simply continues to grow in size. Other techniques, however, reveal that interphase is actually a busy time for a proliferating cell, during which elaborate preparations for cell division are occurring in a tightly ordered sequence. Two critical preparatory events that are completed during interphase are DNA replication and duplication of the *centrosome*.

As discussed in Chapter 17, cyclical oscillations in the activities of the Cdks and of proteolytic complexes drive the cell cycle forward. Cdks trigger various steps of the cycle either by directly phosphorylating structural or regulatory proteins or by activating other protein kinases to do so. The proteolytic complexes activate specific steps in the cycle by degrading key cell-cycle proteins such as cyclins and Cdk inhibitor proteins. Like throwing switches, the activation of Cdks and proteolytic complexes triggers cell-cycle transitions that are normally points of no return. Thus, a green light from M-Cdk to enter M phase results in chromosome condensation, nuclear envelope breakdown, and a dramatic change in microtubule dynamics, all triggered by the phosphorylation of regulatory proteins that control these processes.

It is crucial that the two major events of M phase—nuclear division (mitosis) and cytoplasmic division (cytokinesis)—occur in the correct sequence (see Figure 18-1). It would be catastrophic if cytokinesis occurred before all of the chromosomes had segregated during mitosis. At least two mechanisms seem to prevent this catastrophe. First, the cell-cycle control system that activates proteins required for mitosis is thought to inactivate some of the proteins required for cytokinesis; presumably for this reason, cytokinesis cannot occur until M-Cdk is inactivated at the end of mitosis. Second, after the mitotic spindle has segregated the two sets of chromosomes to opposite poles of the cell, the residual central region of the spindle is required to maintain a functional contractile ring (see Figure 18-4); thus, until the spindle has separated the chromosomes and formed a *central spindle*, the ring cannot divide the cytoplasm in two.  [TOP](#)

M Phase in Animal Cells Depends on Centrosome Duplication in the Preceding Interphase

Two critical events must be completed in interphase before M phase begins—replication of the DNA and, in animal cells, duplication of the centrosome. DNA is duplicated so that each new daughter cell inherits an identical copy of the genome, while the centrosome is duplicated to help

initiate the formation of the two poles of the mitotic spindle and to supply each daughter cell with its own centrosome. As we discuss later, after the chromosomes have been segregated in late mitosis, the microtubules that emanate from the two centrosomes signal to the cell cortex to help establish the plane of cytoplasmic division. This ensures that the division occurs exactly midway between the two separated groups of chromosomes (see [Figure 18-4](#)).

The centrosome is the principal *microtubule-organizing center* in animal cells (discussed in [Chapter 16](#)). It consists of a cloud of amorphous material (called the *centrosome matrix* or *pericentriolar material*) that surrounds a pair of *centrioles* (see [Figure 16-24](#)). During interphase, the centrosome matrix nucleates a *cytoplasmic array* of microtubules, with their fast-growing plus ends projecting outward toward the cell perimeter and their minus ends associated with the centrosome. The matrix contains a great variety of proteins, including microtubule-dependent motor proteins, coiled-coil proteins that are thought to link the motors to the centrosome, structural proteins, and components of the cell-cycle control system. Most important, it contains the **γ -tubulin ring complex**, which is the component mainly responsible for nucleating microtubules (see [Figure 16-22](#)).

The process of centrosome duplication and separation is known as the centrosome cycle. During interphase of each animal cell cycle, the centrioles and other components of the centrosome are duplicated (by an unknown mechanism) but remain together as a single complex on one side of the nucleus ([Figure 18-5](#)). As mitosis begins, this complex splits in two, and each centriole pair becomes part of a separate microtubule organizing center that nucleates a radial array of microtubules called an aster ([Figure 18-6](#)). The two asters move to opposite sides of the nucleus to initiate the formation of the two poles of the mitotic spindle. When the nuclear envelope breaks down (at *prometaphase*), the spindle captures the chromosomes; it will separate them toward the end of mitosis ([Figure 18-7](#)). As mitosis ends and the nuclear envelope re-forms around the separated chromosomes, each daughter cell receives a centrosome in association with its chromosomes.

In early embryonic cell cycles, the centrosome cycle can operate even if the nucleus is physically removed or nuclear DNA replication is blocked by a drug that inhibits DNA synthesis. Cycles of centrosome duplication and separation proceed almost normally, first yielding two centrosomes, then four, and then eight, and so on. Egg cell extracts from the frog *Xenopus* (see [Figure 17-9](#)) support multiple rounds of centrosome duplication in a test tube. This system has been used to test the individual protein components of the cell-cycle control system for their ability to stimulate centrosome duplication. Such experiments show that the G_1/S -Cdk (a complex of cyclin E and Cdk2) that initiates DNA replication in S phase (discussed in [Chapter 17](#)) also stimulates centrosome duplication, presumably explaining why centrosome duplication begins at the start of S phase. [↑ TOP](#)

M Phase Is Traditionally Divided into Six Stages

The first five stages of M phase constitute mitosis, which was originally defined as the period in which the chromosomes are visibly condensed. *Cytokinesis* occurs in the sixth stage, which overlaps with the end of mitosis. These six stages form a dynamic sequence, in which many independent cycles, involving the chromosomes, cytoskeleton, and centrosomes, have to be coordinated in order to produce two genetically identical daughter cells. The stages that occur during M phase are summarized in Panel 18-1. The complexity and beauty of M phase, however, are hard to appreciate from written descriptions or from a set of static pictures.

The five stages of mitosis—*prophase*, *prometaphase*, *metaphase*, *anaphase*, and *telophase*—occur in strict sequential order, while cytokinesis begins in anaphase and continues through telophase. Light micrographs of cell division in a typical animal cell and a typical plant cell are shown in Figures 18-8 and 18-9, respectively. During prophase, the replicated chromosomes condense in step with the reorganization of the cytoskeleton. In metaphase, the chromosomes are aligned at the equator of the mitotic spindle, and in anaphase they are segregated to the two poles of the spindle. Cytoplasmic division is complete by the end of telophase, and the nucleus and cytoplasm of each of the daughter cells then return to interphase, signaling the end of M phase. [↑ TOP](#)

Summary

Cell division occurs during M phase, which consists of nuclear division (mitosis) followed by cytoplasmic division (cytokinesis). The DNA is replicated in the preceding S phase; the two copies of each replicated chromosome (called sister chromatids) remain glued together by cohesins. At the start of M phase, cohesin-related proteins called condensins bind to the replicated chromosomes and progressively condense them. A microtubule-based mitotic spindle is responsible for chromosome segregation in all eucaryotic cells. The mitotic spindle in animal cells develops from the microtubule asters that form around each of the two centrosomes produced when the centrosome duplicates, beginning in S phase; at the onset of M phase, the duplicated centrosomes separate and move to opposite sides of the nucleus to initiate the formation of the two poles of the spindle. An actin and myosin-based contractile ring is responsible for cytoplasmic division in animal cells and in many unicellular eucaryotes, but not in plant cells. [↑ TOP](#)

Figure 18-5. Centrioles. (A) Electron micrograph of an S-phase mammalian cell in culture, showing a duplicated centrosome. Each centrosome contains a pair of centrioles; although the centrioles have duplicated, they remain together in a single complex, as shown in the drawing of the micrograph in (B). One centriole of each centriole pair has been cut in cross-section, while the other is cut in longitudinal section, indicating that the two members of each pair are aligned at right angles to each other. The two halves of the replicated centrosome, each consisting of a centriole pair surrounded by matrix, will split and migrate apart to

initiate the formation of the two poles of the mitotic spindle when the cell enters M phase (see [Figure 18-7](#)). (C) Electron micrograph of a centriole pair that has been isolated from a cell. The two centrioles have partly separated during the isolation procedure but remain tethered together by fine fibers, which keep the centriole pair together until it is time for them to separate (see [Figure 18-6](#)). Both centrioles are cut longitudinally, and it can now be seen that the two have different structures: the mother centriole is larger and more complex than the daughter centriole, and, as shown in [Figure 18-6](#), only the mother centriole is associated with matrix that nucleates microtubules. Each daughter centriole will mature during the next cell cycle, when it will replicate to give rise to its own daughter centriole. (A, from M. McGill, D.P. Highfield, T.M. Monahan, and B.R. Molecular Biology of the Cell → **IV. Internal Organization of the Cell** → 18. The Mechanics of Cell Division → An Overview of M Phase

Figure 18-7. The centrosome cycle. The centrosome in a proliferating animal cell duplicates in interphase in preparation for mitosis. In most animal cells, a centriole pair (shown here as a pair of *dark green bars*) is associated with the centrosome matrix (*light green*) that nucleates microtubule outgrowth. (The volume of centrosome matrix is exaggerated in this diagram for clarity; [Figure 18-6](#) gives a more accurate representation.) Centriole duplication begins in G_1 and is completed by G_2 (see [Figure 18-6](#)). Initially the two centriole pairs and associated centrosome matrix remain together as a single complex. In early M

phase, this complex separates into two, each of which nucleates its own aster. The two asters, which initially lie side by side and close to the nuclear envelope, move apart. By late prophase, the microtubules that interact between the two asters preferentially elongate as the two asters move apart along the outside of the nucleus. In this way, a bipolar mitotic spindle is rapidly formed. At metaphase, the nuclear envelope breaks down, enabling the spindle microtubules to interact with the chromosomes.

Figure 18-8. The course of mitosis in a typical animal cell. In these micrographs of cultured newt lung cells, the microtubules (*green*) have been visualized by immunofluorescence, while the chromatin is stained with a *blue* fluorescent dye.

During *interphase*, the centrosome (not visible) forms the focus for the interphase microtubule array. By *early prophase*, the single centrosome contains two centriole pairs (not visible). At *late prophase*, the centrosome divides, and the resulting two asters can be seen to have moved apart. At *prometaphase*, the nuclear envelope breaks down, allowing the spindle microtubules to interact with the fully condensed chromosomes. At *metaphase*, the bipolar structure of the spindle is clear, and all the chromosomes are aligned at the equator of the spindle. At *early anaphase*, the sister chromatids all separate synchronously and, under the influence of the microtubules, the daughter chromosomes begin to move toward the poles. By *late anaphase*, the spindle poles have moved farther apart, increasing the separation of the two groups of chromosomes. At *telophase*, the daughter nuclei re-form, and by *late telophase*, cytokinesis is almost complete, with the midbody (discussed later) persisting between the daughter cells. 18-1. The Principal Stages of M Phase (Mitosis and Cytokinesis) in an Animal Cell

CELL DIVISION AND THE CELL CYCLE

The division of a cell into two daughters occurs in the M phase of the cell cycle. M phase consists of nuclear division (mitosis) and cytoplasmic division (cytokinesis).

INTERPHASE

During interphase, the cell increases in size. The DNA of the chromosomes is replicated, and the centrosome is duplicated.

The light micrographs shown in this panel are of a living cell from the lung epithelium of a newt. The same cell has been photographed when viewed by

In this figure, the M phase has been expanded for clarity. Mitosis is itself divided into five stages, and these, together with cytokinesis, are described in this panel.

differential-interference-contrast microscopy at different times during its division into two daughter cells. (Courtesy of Conly L. Rieder.)

1 PROPHASE

At **prophase**, the replicated chromosomes, each consisting of two closely associated sister chromatids, condense. Outside the nucleus, the mitotic spindle assembles between the two centrosomes, which have replicated and moved apart. For simplicity, only three chromosomes are shown. In diploid cells, there would be two copies of each chromosome present.

time = 0 min

2 PROMETAPHASE

Prometaphase starts abruptly with the breakdown of the nuclear envelope. Chromosomes can now attach to spindle microtubules via their kinetochores and undergo active movement.

time = 79 min

3 METAPHASE

At **metaphase**, the chromosomes are aligned at the equator of the spindle, midway between the spindle poles. The kinetochore microtubules

attach sister chromatids to opposite poles of the spindle.

time = 250 min

4 ANAPHASE

At **anaphase**, the sister chromatids synchronously separate to form two daughter chromosomes, and each is pulled slowly toward the spindle pole it faces. The kinetochore microtubules get shorter, and the spindle poles also move apart; both processes contribute to chromosome separation.

time = 279 min

5 TELOPHASE

During **telophase**, the two sets of daughter chromosomes arrive at the poles of the spindle and decondense. A new nuclear envelope reassembles around each set, completing the formation of two nuclei and marking the end of mitosis. The division of the cytoplasm begins with the assembly of the contractile ring.

time = 315 min

Mitosis

The segregation of the replicated chromosomes is brought about by a complex cytoskeletal machine with many moving parts—the mitotic spindle. It is constructed from microtubules and their associated proteins, which both pull the daughter chromosomes toward the poles of the spindle and move the poles apart.

As we have seen, the spindle starts to form outside the nucleus while the chromosomes are condensing during prophase. When the nuclear envelope breaks down at prometaphase, the microtubules of the spindle are able to capture the chromosomes, which eventually become aligned at the spindle equator, forming the *metaphase plate* (see [Panel 18-1](#)). At anaphase, the sister chromatids abruptly separate and are drawn to opposite poles of the spindle; at about the same time, the spindle elongates, increasing the separation between the poles. The spindle continues to elongate during telophase, as the chromosomes arriving at the poles are released from the spindle microtubules and the nuclear envelope re-forms around them.

Both the assembly and the function of the mitotic spindle depend on **microtubule-dependent motor proteins**. As discussed in [Chapter 16](#), these proteins belong to two families—the **kinesin-related proteins**, which usually move toward the plus end of microtubules, and the **dyneins**, which move toward the minus end. In the mitotic spindle, the motor proteins operate at or near the ends of the microtubules. These ends are not only sites of microtubule assembly and disassembly; they are also sites of force production. The assembly and dynamics of the mitotic spindle rely on the shifting balance between opposing plus-end-directed and minus-end-directed motor proteins.

Three classes of spindle microtubules can be distinguished in mitotic animal cells ([Figure 18-10](#)). Astral microtubules radiate in all directions from the centrosomes and are thought to contribute to the forces that separate the poles. They also act as "handles" for orienting and positioning the spindle in the cell. Kinetochores attach end-on to the *kinetochore*, which forms at the *centromere* of each duplicated chromosome. They serve to attach the chromosomes to the spindle. Overlap microtubules interdigitate at the equator

of the spindle and are responsible for the symmetrical, bipolar shape of the spindle. All three classes of microtubules have their plus ends projecting away from their centrosome. The behavior of each class is thought to be different because of the different protein complexes that are associated with their plus and minus ends.

Microtubule Instability Increases Greatly at M Phase

The mitotic spindle begins to self-assemble in the cytoplasm during prophase. In animal cells, each of the replicated centrosomes nucleates its own array of microtubules, and the two sets of microtubules interact to form the mitotic spindle. We see later that the self-assembly process depends on a balance between opposing forces that originate within the spindle itself and are generated by motor proteins associated with the spindle microtubules.

Many animal cells in interphase contain a cytoplasmic array of microtubules radiating out from the single centrosome. As discussed in Chapter 16, the microtubules of this *interphase array* are in a state of dynamic instability, in which individual microtubules are either growing or shrinking and stochastically switch between the two states. The switch from growth to shrinkage is called a *catastrophe*, and the switch from shrinkage to growth is called a *rescue* (see Figure 16-11). New microtubules are continually being created to balance the loss of those that disappear completely by depolymerization.

Prophase signals an abrupt change in the cell's microtubules. The relatively few, long microtubules of the interphase array rapidly convert to a larger number of shorter and more dynamic microtubules surrounding each centrosome, which will begin to form the mitotic spindle. During prophase, the half-life of microtubules decreases dramatically. This can be seen by labeling the microtubules in living cells with fluorescent tubulin subunits (Figure 18-11). As the instability of microtubules increases, the number of microtubules radiating from the centrosomes greatly increases as well, apparently because of an alteration in the centrosomes themselves that increases the rate at which they nucleate new microtubules. How does the cell-cycle control system trigger these dramatic changes in the cell's microtubules at the onset of mitosis?

M-Cdk initiates the changes by causing the phosphorylation of two classes of proteins that control microtubule dynamics (discussed in Chapter 16). These include microtubule motor proteins and **microtubule-associated proteins (MAPs)**. The roles of these regulators in controlling microtubule dynamics have been revealed by experiments using *Xenopus* egg extracts, which reproduce many of the changes that occur in intact cells during M phase. If centrosomes and fluorescent tubulin are mixed with extracts made from either M-phase or interphase cells, fluorescent microtubules nucleate from the centrosomes, permitting the behavior of individual microtubules to be analyzed by time-lapse fluorescence video microscopy. The microtubules in

mitotic extracts differ from those in interphase extracts primarily by the increased rate of catastrophes, where they switch abruptly from slow growth to rapid shortening.

Proteins called **catastrophins** destabilize microtubule arrays by increasing the frequency of catastrophes (see [Figure 16-36A](#)). Among the catastrophins is a kinesin-related protein that does not function as a motor. In general, MAPs have the opposite effect of catastrophins, stabilizing microtubules in various ways: they can increase the frequency of rescues, in which microtubules switch from shrinkage to growth, or they can either increase the growth rate or decrease the shrinkage rate of microtubules. Thus, in principle, changes in catastrophins and MAPs can make microtubules much more dynamic in M phase by increasing total microtubule depolymerization rates, decreasing total microtubule polymerization rates, or both.

In *Xenopus* egg extracts, the balance between a single type of catastrophin and a single type of MAP can be shown to determine the catastrophe rate and the steady-state length of microtubules. This balance, in turn, governs the assembly of the mitotic spindle, as microtubules that are either too long or too short are incapable of assembling into a spindle ([Figure 18-12](#)). One way in which M-Cdk may control microtubule length is by phosphorylating this MAP and reducing its ability to stabilize microtubules. Even if the activity of the catastrophin remained constant throughout the cell cycle, the balance between the two opposing activities of the MAP and catastrophin would shift, increasing the dynamic instability of the microtubules.

The cell contains a variety of MAPs, catastrophins, and motor proteins, each with subtly different activities. It is the balance between the opposing activities of these proteins that is responsible for the dynamic behavior of the mitotic spindle. We see later how changes in this balance help the spindle to segregate the chromosomes at anaphase. [↑ TOP](#)

Interactions Between Opposing Motor Proteins and Microtubules of Opposite Polarity Drive Spindle Assembly

While a shift in the balance between MAPs and catastrophins early in M phase creates more dynamic microtubules, a different sort of balance, between minus-end-directed and plus-end-directed motor proteins, helps assemble the mitotic spindle. Because some of these motor proteins form oligomers that can cross-link adjacent microtubules, they can move one microtubule relative to the other, with the direction of movement dependent on the polarity of both the motor protein and the microtubules. In this way, these motor proteins can form foci by bringing together a group of microtubule ends ([Figure 18-13A](#)).

Alternatively, such motor proteins can slide antiparallel microtubules past each other ([Figure 18-13B](#)). These two different motor protein functions play a crucial part in the assembly and function of the spindle: they create the foci of microtubule minus ends that form the two spindle poles, and they slide

antiparallel microtubules past each other in the overlap zone of the spindle (see [Figure 18-10](#)).

During prophase in animal cells, microtubules growing from one centrosome engage with the microtubules of the adjacent centrosome. Because the plus ends of the microtubules are oriented away from the centrosomes, these two sets of microtubules have opposite polarities. Plus-end-directed motor proteins cross-link the two sets of microtubules and help push the centrosomes apart to begin to form the two poles of the mitotic spindle ([Figure 18-14](#)). A balance between plus-end-directed motor proteins and minus-end-directed motor proteins is crucial for spindle assembly: whereas plus-end-directed motor proteins operating on overlap microtubules tend to push the two halves of the spindle apart, some minus-end-directed motor proteins tend to pull them together.

At least seven families of kinesin-related motor proteins have been localized to the mitotic spindle in vertebrate cells. In the budding yeast *S. cerevisiae*, five such motor proteins have been shown to work together in the spindle. Increasing the level of one of the plus-end-directed motor proteins produces abnormally long spindles, whereas increasing the level of one of the minus-end-directed motor proteins produces abnormally short spindles ([Figure 18-15](#)). Thus, the balance between plus-end-directed and minus-end-directed motor proteins seems to determine spindle length. A similar balance between motor proteins of opposite polarities occurs in human mitotic cells. At least, one of the motor proteins in human cells has to be phosphorylated by M-Cdk to bind to the spindle, suggesting one way in which M-Cdk might control the balance between opposing motor proteins. [↑ TOP](#)

Kinetochores Attach Chromosomes to the Mitotic Spindle

Prometaphase in animal cells begins abruptly with the breakdown of the nuclear envelope. The breakdown is triggered when M-Cdk directly phosphorylates the nuclear lamina that underlies the nuclear envelope (see [Figure 12-20](#)). The disassembly of the nuclear envelope allows the microtubules access to the condensed chromosomes for the first time. Now, the assembly of a mature mitotic spindle can begin (see [Panel 18-1](#), pp. 1034–1035).

The attachment of the chromosomes to the spindle is a dynamic process. When viewed by video microscopy, it seems to involve a "search and capture" mechanism, in which microtubules nucleated from each of the rapidly separating centrosomes grow outward toward the chromosomes. Microtubules that attach to a chromosome become stabilized, so that they no longer undergo catastrophes. They eventually end up attached end-on at the kinetochore, a complex protein machine that assembles onto the highly condensed DNA at the centromere (discussed in [Chapter 4](#)) during late prophase. The end-on attachment to the kinetochore is through the plus end of the microtubule,

which is now called a *kinetochore microtubule* ([Figure 18-16](#)).

In newt lung cells, where the initial capture event can be readily visualized, the kinetochore is seen first to bind to the side of the microtubule and then to slide rapidly along it toward one of the centrosomes. The lateral attachment to the chromosome is rapidly converted to an end-on attachment. At the same time, microtubules growing from the opposite spindle pole attach to the kinetochore on the opposite side of the chromosome, forming a *bipolar attachment* ([Figure 18-17](#)). Then begins a truly mesmerizing stage of mitosis. First, the chromosomes are tugged back and forth, eventually assuming a position equidistant between the two spindle poles, a position called the *metaphase plate* ([Figure 18-18](#)). In vertebrate cells, the chromosomes then oscillate gently at the metaphase plate, awaiting the signal to separate. The signal is produced after a predictable lag time after the bipolar attachment of the last of the chromosomes (discussed in [Chapter 17](#)).

As we discuss later, kinetochores play a crucial part in moving chromosomes on the spindle. They have a platelike organization when viewed in the electron microscope ([Figure 18-19](#)), and they are associated with both plus-end-directed and minus-end-directed microtubule motor proteins. But it remains a mystery how the plus ends of microtubules are attached to the kinetochore, especially because these ends are continuously polymerizing or depolymerizing, depending on the stage of mitosis. [↑ TOP](#)

Microtubules Are Highly Dynamic in the Metaphase Spindle

The *metaphase* spindle is a complex and beautiful assembly, suspended in a state of dynamic equilibrium and tensed for action that will begin in anaphase. All of the spindle microtubules, except the kinetochore microtubules, are in a state of dynamic instability, with their free plus ends shifting stochastically between slow growth and rapid shrinkage. In addition, the kinetochore and overlap microtubules exhibit a behavior called *poleward flux*, with a net addition of tubulin subunits at their plus end, balancing a net loss at their minus ends, near the spindle poles.

The poleward flux in kinetochore and overlap microtubules in metaphase spindles has been studied directly by allowing the microtubules to incorporate tubulin that has been covalently coupled to photoactivatable, "caged" fluorescein. When such spindles are marked with a beam of UV light from a laser, the marks move continuously toward the spindle poles ([Figure 18-20](#)). The fluorescent marks get dimmer with time, indicating that many of the overlap and kinetochore microtubules depolymerize completely and are replaced. The dynamics of individual spindle microtubules of all classes (astral, kinetochore, and overlap) can be studied by an ingenious method in which very low amounts of fluorescent tubulin are injected into living cells ([Figure 18-21](#)). In these studies, a poleward flux is seen in both kinetochore

and overlap microtubules, but not in astral microtubules. The function of the poleward flux, which does not occur in simple spindles such as those in yeasts, is unknown, although it might aid chromosome movement in anaphase.

One of the most striking aspects of metaphase in vertebrate cells is the continuous oscillatory movement of the chromosomes at the metaphase plate. These movements have been studied by video microscopy in newt lung cells and are seen to switch between two states—a poleward (P) state, which is a minus-end-directed pulling movement, and an away-from-the-pole (AP) state, which is a plus-end-directed movement. Kinetochores are thought to pull the chromosomes toward the poles, while an *astral ejection force* is thought to push the chromosomes away from the poles, toward the spindle equator (Figure 18-22A). Plus-end-directed motor proteins located on the chromosome arms are believed to interact with the astral microtubules to produce the ejection force (Figure 18-22B). Interestingly, spindles without centrosomes, including those in higher plants and some meiotic spindles, do not display these oscillations, which might reflect the absence of astral microtubules and, consequently, the absence of the astral ejection force. [↑ TOP](#)

Functional Bipolar Spindles Can Assemble Around Chromosomes in Cells Without Centrosomes

Chromosomes are not just passive passengers in the process of spindle assembly. By creating a local environment that favors both microtubule nucleation and microtubule stabilization, they play an active part in spindle formation. The influence of the chromosomes can be demonstrated by using a fine glass needle to reposition them after the spindle has formed. For some cells in metaphase, if a single chromosome is tugged out of alignment, a mass of new spindle microtubules rapidly appears around the newly positioned chromosome, while the spindle microtubules at the chromosome's former position depolymerize. This property of the chromosomes seems to depend on a guanine-nucleotide exchange factor (GEF) that is bound to chromatin; it stimulates a small GTPase in the cytosol called *Ran*, inducing *Ran* to bind GTP in place of GDP. The activated *Ran*–GTP, which is also involved in nuclear transport (discussed in [Chapter 12](#)), releases microtubule-stabilizing proteins from protein complexes in the cytosol, thereby stimulating the local nucleation of microtubules around chromosomes.

In cells without centrosomes, the chromosomes direct the assembly of a functional bipolar spindle. This is how spindles form in cells of higher plants, as well as in many meiotic cells. It is also how they assemble in certain insect embryos that have been induced to develop from eggs without fertilization (i. e., *parthenogenetically*); as the sperm normally provides the centrosome when it fertilizes an egg (discussed in [Chapter 20](#)), the mitotic spindles in these parthenogenic embryos develop without centrosomes (Figure 18-23). Remarkably, in artificial systems, spindles can self-assemble without either centrosomes or centromeres. When beads coated with DNA that lack

centromere sequences (and therefore lack kinetochore complexes) are added to *Xenopus* egg extracts in the absence of centrosomes, bipolar spindles assemble around the beads ([Figure 18-24A](#)).

The centrosome-independent spindle assembly process is different from the assembly that is directed by centrosomes. In the DNA-coated bead model, for example, the microtubules first nucleate near the surface of the DNA, and then microtubule motor proteins sort the microtubules into bundles of uniform polarity, push the minus ends of the microtubules apart, and focus them into spindle poles ([Figure 18-24B](#)).

Even vertebrate cells can use such a centrosome-independent pathway to construct a functional bipolar spindle if the centrosomes are destroyed with a laser beam. Although the resulting acentrosomal spindle can segregate chromosomes normally, it lacks astral microtubules, which are responsible for positioning the spindle in animal cells; as a result, the spindle is often mispositioned, resulting in abnormalities in cytokinesis. If present, however, centrosomes normally direct spindle assembly because they are more efficient at nucleating microtubule polymerization than are chromosomes. [↑ TOP](#)

Anaphase Is Delayed Until All Chromosomes Are Positioned at the Metaphase Plate

Mitotic cells usually spend about half of M phase in metaphase, with the chromosomes aligned on the metaphase plate, jostling about, awaiting the signal that induces sister chromatids to separate to begin anaphase. Treatment with drugs that destabilize microtubules, such as colchicine or vinblastine (discussed in [Chapter 16](#)), arrests mitosis for hours or even days. This observation led to the identification of a [spindle-attachment checkpoint](#), which is activated by the drug treatment and arrests progress in mitosis. The checkpoint mechanism is used by the cell-cycle control system to ensure that cells do not enter anaphase until all chromosomes are attached to both poles of the spindle (discussed in [Chapter 17](#)). If one of the protein components of the checkpoint mechanism is inactivated by mutation or by an intracellular injection of antibodies against the component, the cells initiate anaphase prematurely.

The spindle-attachment checkpoint monitors the attachment of the chromosomes to the mitotic spindle. It is thought to detect either unattached kinetochores or kinetochores that are not under the tension that results from bipolar attachment. In either case, unattached kinetochores emit a signal that delays anaphase until they all are properly attached to the spindle (see [Figure 17-27](#)). Drugs that destabilize microtubules prevent such attachment and therefore maintain the signal and delay anaphase. The inhibitory signaling role of the kinetochore can be demonstrated in mammalian cells in culture, where a single unattached kinetochore can block anaphase; destruction of this

kinetochore with a laser causes the cell to enter anaphase. [↑ TOP](#)

Sister Chromatids Separate Suddenly at Anaphase

Anaphase begins abruptly with the release of the cohesin linkage that holds the sister chromatids together at the metaphase plate. As discussed in [Chapter 17](#), this *metaphase-to-anaphase transition* is triggered by the activation of the *anaphase promoting complex (APC)*. Once this proteolytic complex is activated, it has at least two crucial functions: (1) it cleaves and inactivates the M-phase cyclin (M-cyclin), thereby inactivating M-Cdk; and (2) it cleaves an inhibitory protein (securin), thereby activating a protease called *separase*. Separase then cleaves a subunit in the cohesin complex to unglue the sister chromatids (see [Figure 17-26](#)). The sisters immediately separate—and are now called daughter chromosomes—and move to opposite poles ([Figure 18-25](#)).

The chromosomes move by two independent and overlapping processes. The first, referred to as **anaphase A**, is the initial poleward movement of the chromosomes. It is accompanied by shortening of the kinetochore microtubules at their attachment to the chromosome and, to a lesser extent, by the depolymerization of spindle microtubules at the two spindle poles. The second process, referred to as **anaphase B**, is the separation of the poles themselves, which begins after the sister chromatids have separated and the daughter chromosomes have moved some distance apart. Anaphase A depends on motor proteins at the kinetochore. Anaphase B depends on motor proteins at the poles that pull the poles apart, as well as on motor proteins at the *central spindle* (the bundles of antiparallel overlap microtubules between the separating chromosomes) that push the poles apart ([Figure 18-26](#)). Originally, anaphase A and anaphase B were distinguished by their different sensitivities to drugs. These differences are now thought to reflect differences in the sensitivities of the microtubule motor proteins that mediate the two processes. [↑ TOP](#)

Kinetochore Microtubules Disassemble at Both Ends During Anaphase A

As each daughter chromosome moves poleward, its kinetochore microtubules depolymerize, so that they have nearly disappeared at telophase. We can see this process by fluorescence video microscopy, in which labeled tubulin is injected into cells so that the sites of recent tubulin incorporation can be seen. In such experiments, the kinetochore ends of the kinetochore microtubules are observed to be the primary sites of tubulin addition during metaphase. In anaphase A, however, the kinetochore microtubules shorten mainly by the loss of tubulin from their kinetochore ends. It is not known how this switch from polymerization to depolymerization at kinetochores occurs at anaphase, but it may be triggered by the loss of tension that occurs when the cohesion between the sister chromatids is destroyed.

The poleward flux discussed earlier, with the continuous loss of tubulin subunits from both the overlap and kinetochore microtubules at the poles (see [Figure 18-21](#)), continues through anaphase. Thus, the kinetochore microtubules disassemble from both ends in anaphase.

Although it is clear that both microtubule motor proteins and microtubule depolymerization at the kinetochores contribute to chromosome movement during anaphase A, the exact molecular mechanism that drives the movement is still unknown. It is also unclear how kinetochores can remain attached to a microtubule that is losing tubulin subunits at its kinetochore (plus) end. There are two main ideas about how chromosomes move in anaphase A. One is that motor proteins at the kinetochores use the energy of ATP hydrolysis to pull the chromosomes along the kinetochore microtubules, which depolymerize as a consequence. Another is that the depolymerization itself drives the movement, without using ATP ([Figure 18-27](#)). The second possibility might seem implausible at first, but it has been shown that purified kinetochores in a test tube, with no ATP present, can remain attached to depolymerizing microtubules and thereby move. The energy that drives the movement is stored in the microtubule and is released when the microtubule depolymerizes; it ultimately comes from the hydrolysis of GTP that occurs after a tubulin subunit adds to the end of a microtubule (discussed in [Chapter 16](#)). How motor proteins and microtubule depolymerization at the kinetochore combine to drive chromosome movement remains one of the fundamental mysteries of mitosis. [↑ TOP](#)

Both Pushing and Pulling Forces Contribute to Anaphase B

In anaphase B, the spindle elongates, pulling the two sets of chromosomes farther apart. In contrast to anaphase A, where the depolymerization of kinetochore microtubules is coupled to chromosome movement toward the poles, in anaphase B, the overlap microtubules actually elongate, helping to push the spindle poles apart. Anaphase B is driven by two distinct forces (see [Figure 18-26](#)). The first depends on plus-end-directed microtubule motor proteins in the central spindle that form a bridge between the overlapping microtubules of opposite polarities; the translocation of these motors toward the microtubule plus ends slides the microtubules past one another, pushing the poles apart. As a result, the bundle of overlap microtubules in the central spindle thins out ([Figure 18-28](#)). This mechanism is similar to that described earlier, in which motor proteins push the poles apart during spindle assembly in prophase (see [Figure 18-14](#)). The second force contributing to anaphase B depends on minus-end-directed motor proteins that interact with both the astral microtubules and the cell cortex and pull the two poles of the spindle apart ([Figure 18-29](#)).

The relative contributions of anaphase A and anaphase B to chromosome segregation vary greatly, depending on the cell type. In mammalian cells, anaphase B begins shortly after anaphase A and stops when the spindle is

about twice its metaphase length; in contrast, the spindles of yeasts and certain protozoa primarily use anaphase B to separate the chromosomes at anaphase, and their spindles elongate to up to 15 times the metaphase length in the process. [↑ TOP](#)

At Telophase, the Nuclear Envelope Re-forms Around Individual Chromosomes

By the end of anaphase, the daughter chromosomes have separated into two equal groups at opposite ends of the cell and have begun to decondense. In telophase, the final stage of mitosis, a nuclear envelope reassembles around each group of chromosomes to form the two daughter interphase nuclei.

The sudden transition from metaphase to anaphase initiates the dephosphorylation of the many proteins that were phosphorylated at prophase. Although the relevant phosphatases are active throughout mitosis, it is not until M-Cdk is switched off that the phosphatases can act unopposed. Shortly thereafter, at telophase, nuclear membrane fragments associate with the surface of individual chromosomes and fuse to re-form the nuclear envelope. Initially, the fused membrane fragments partly enclose clusters of chromosomes; the fragments then coalesce to re-form the complete nuclear envelope (see [Figure 12-21](#)). During this process, the nuclear pore complexes are incorporated into the envelope, and the dephosphorylated lamins reassociate to form the nuclear lamina. The nuclear envelope once again becomes continuous with the extensive membrane sheets of the endoplasmic reticulum. Once the nuclear envelope has re-formed, the pore complexes pump in nuclear proteins, the nucleus expands, and the condensed mitotic chromosomes decondense into their interphase state, thereby allowing gene transcription to resume. A new nucleus has been created, and mitosis is complete. All that remains is for the cell to complete its division into two. [↑ TOP](#)

Summary

Mitosis begins with prophase, which is marked by an increase in microtubule instability, triggered by M-Cdk. In animal cells, an unusually dynamic microtubule array (an aster) forms around each of the duplicated centrosomes, which separate to initiate the formation of the two spindle poles. Interactions between the asters and a balance between minus-end-directed and plus-end-directed microtubule-dependent motor proteins result in the self-assembly of the bipolar spindle. In higher-plant cells and other cells that lack centrosomes, a functional, bipolar spindle self-assembles instead around the replicated chromosomes. Prometaphase begins with the breakdown of the nuclear envelope, which allows the kinetochores on the condensed chromosomes to capture and stabilize microtubules from each spindle pole. The kinetochore microtubules from opposite spindle poles pull in opposite directions on each duplicated chromosome, creating, together with a polar ejection force, a tension that helps bring the chromosomes to the spindle equator to form the

metaphase plate. The spindle microtubules at metaphase are highly dynamic and undergo a continuous poleward flux of tubulin subunits. Anaphase begins with the sudden proteolytic cleavage of the cohesin linkage holding sister chromatids together. The breakage of this linkage allows the chromosomes to be pulled to opposite poles (the anaphase A movement). At about the same time, the two spindle poles move apart (the anaphase B movement). In telophase, the nuclear envelope re-forms on the surface of each group of separated chromosomes as the proteins phosphorylated at the onset of M phase are dephosphorylated. [↑ TOP](#)

Figure 18-10. The three classes of microtubules of the fully formed mitotic spindle in an animal cell. (A) In reality, the chromosomes are proportionally much larger than shown in this drawing, and multiple microtubules are attached to each kinetochore. Note that the plus ends of the microtubules project away from the centrosomes, while the minus ends are anchored at the spindle poles. Although the centrosomes initiate the assembly of the spindle poles, most of the kinetochore and overlap microtubules that they nucleate are released from the centrosomes and are then held and organized at the poles by motor proteins. For simplicity, in the other figures in this chapter, we draw all the spindle microtubules at the poles emanating from the centrosomes. (B) A phase-contrast micrograph of an isolated mitotic spindle at metaphase, with the chromosomes aligned at the spindle equator. (B, from E.D. Salmon and R.R.

Figure 18-11. The half-life of microtubules in mitosis. Microtubules in an M-phase cell are much more dynamic, on average, than the microtubules at interphase. Mammalian cells in culture were injected with tubulin that had been covalently linked to a fluorescent dye. After the fluorescent tubulin had become incorporated into the cell's microtubules, an intense laser beam was used to bleach all the fluorescence in a small region. The recovery of fluorescence in the bleached region of microtubules, caused by their replacement by microtubules formed from unbleached fluorescent tubulin from the soluble pool, was then monitored as a function of time. The time for 50% recovery of fluorescence ($t_{1/2}$) is thought to be equal to the time required for half of the microtubules in the region to depolymerize and re-form. (Data from W.M. Saxton et al., *J. Cell Biol.* 99:2175–2187, 1984. © The Rockefeller University Press.)

Mitosis

Figure 18-12. Experimental evidence that the balance between catastrophins and MAPs influences the frequency of microtubule catastrophes and microtubule length. (A) Interphase or mitotic *Xenopus* egg extracts were incubated with centrosomes, and the behavior of individual microtubules nucleated from the centrosomes was followed by fluorescence video microscopy. As expected, the catastrophe rate is higher in mitotic than in interphase extracts. The depletion of a specific MAP (XMAP215) from the mitotic extracts greatly increases the catastrophe rate, indicating that this MAP normally inhibits catastrophes in mitotic extracts. The addition of antibodies that block the function of a specific catastrophin (the kinesin-related protein XKCM1) greatly reduces the catastrophe rate in the XMAP215-depleted mitotic extracts, indicating that this catastrophin is normally responsible for stimulating catastrophes in mitotic extracts and that the catastrophe rate depends on the balance between the MAP and the catastrophin. Fluorescence micrographs of the asters formed in the different experimental conditions are shown in the top panels; note that the higher the catastrophe rates, the shorter the microtubules. (B) Mitotic spindle formation in mitotic extracts when both centrosomes and sperm nuclei are added. Microtubules are shown in red and chromosomes in blue. Whereas normal spindles form in normal mitotic extracts, very abnormal spindles form when XMAP215 is depleted from the extracts, presumably because the microtubules nucleated by the centrosomes are too short. Remarkably, microtubules formed in a test tube from a mixture of purified tubulin, XMAP215, and XKCM1 exhibit normal dynamic instability. (From R. Tournebize et al., *Nature Cell Biol.* 2:13–19, 2000. © Macmillan Magazines Ltd.)

Figure 18-13. Two functions of multimeric motor proteins that are important for mitotic spindle assembly and function. Microtubule-dependent motor proteins hydrolyze ATP and move along a microtubule toward either its plus or its minus end. If the motor protein is multimeric, as in these examples, it can cross-link two adjacent microtubules and move them relative to one another. (A) Some minus-end-directed multimeric motor proteins rearrange microtubules to form a focus of minus ends, where the motor proteins accumulate. (B) If microtubules are aligned so that they are antiparallel (that is, their plus ends are facing in opposite directions), a cross-linking motor protein can slide the microtubules past each other, as shown here for a plus-end-directed motor protein that could elongate the spindle. (Adapted from A.A. Hyman and E. Karsenti, *Cell* 84:406–410, 1996.)

Figure 18-14. Separation of the two spindle poles in prophase in an animal cell. In this model, plus-end-directed motor proteins operating on interacting antiparallel microtubules help separate the two poles of a forming mitotic spindle. New microtubules grow out in random directions from two nearby centrosomes. The microtubules are anchored at the centrosome by their minus ends, while their plus ends extend outward. When two microtubules from opposite centrosomes interact in an overlap zone, plus-end-directed, kinesin-related motor proteins cross-link the microtubules together and tend to

drive the microtubules in the direction that will push the centrosomes apart (see [Figure 18-13B](#)). Minus-end-directed dynein motors associated with the nuclear envelope are also thought to help separate the two centrosomes by pulling on the two sets of astral microtubules (not shown).

Figure 18-15. The influence of opposing motor proteins on spindle length in budding yeast. (A) A differential-interference-contrast micrograph of a mitotic yeast cell. The spindle is highlighted in *green*, and the position of the spindle poles is indicated by *red arrows*. The nuclear envelope does not break down during mitosis in yeasts, and the spindle forms inside the nucleus (see [Figure 18-41](#)). In (B–D), the mitotic spindles have been stained with fluorescent anti-tubulin antibodies. (B) Normal yeast cells. (C) Over-expression of the minus-end-directed motor protein Kar3p leads to abnormally short spindles. (D) Overexpression of the plus-end-directed motor protein Cin8p leads to abnormally long spindles. Thus, it seems that a balance between opposing motor proteins determines spindle length in these cells. (A, courtesy of Kerry Bloom; B–D, from W. Saunders, V. Lengyel, and M.A. Hoyt, *Mol. Biol. Figure 18-20. The dynamic behavior of microtubules in the metaphase spindle studied by photoactivation of fluorescence. A metaphase spindle formed *in vitro* by adding *Xenopus* sperm to an extract of *Xenopus* eggs (see Figure 17-9) has incorporated three fluorescent markers: rhodamine-labeled tubulin (red) to mark all of the microtubules, a blue DNA-binding dye that labels the chromosomes, and caged-fluorescein-labeled tubulin, which is also incorporated into all of the microtubules but is invisible because it is nonfluorescent until activated by ultraviolet light. (A) The distribution of the

chromosomes and microtubules in the spindle. (B) A beam of ultraviolet light was used to uncage the caged-fluorescein-labeled tubulin locally, mainly just to the left side of the metaphase plate. Over the next few minutes (after 1.5 minutes in C, after 2.5 minutes in D), the uncaged fluorescein-tubulin signal is seen to move toward the left spindle pole, indicating that tubulin is continuously moving poleward, even though the spindle (visualized by the *red* rhodamine-tubulin fluorescence) remains largely unchanged. The caged fluorescein signal also diminishes in intensity, indicating that the individual microtubules are continually depolymerizing and being replaced. (From K.E. Sawin and T.J. Mitchison, *J. Cell Biol.* 112:941–954, 1991. © The Rockefeller University Press.)

Figure 18-22. How opposing forces may drive chromosomes to the metaphase plate. (A) Evidence for an astral ejection force that pushes chromosomes away from the spindle poles toward the spindle equator. In this experiment, a prometaphase chromosome that is temporarily attached to a single pole by kinetochore microtubules is cut in half with a laser beam. The half that is freed from the kinetochore is pushed rapidly away from the pole, whereas the half that remains attached to the kinetochore moves toward the pole, reflecting a decreased repulsion. (B) A model of how two opposing forces may cooperate to move chromosomes to the metaphase plate. Plus-end-directed motor proteins on the chromosome arms are thought to interact with astral microtubules to generate the astral ejection force, which pushes chromosomes toward the spindle equator. Minus-end-directed motor proteins at the kinetochore are thought to interact with kinetochore microtubules to pull chromosomes toward the pole.

Molecular Biology of the Cell ➔ IV. Internal Organization of the Cell ➔ 18. The Mechanics of Cell Division ➔ Mitosis

Figure 18-26. The major forces that separate daughter chromosomes at anaphase in mammalian cells. Anaphase A depends on motor proteins operating at the kinetochores that, together with the depolymerization of the kinetochore microtubules, pull the

daughter chromosomes toward the nearest pole. In anaphase B, the two spindle poles move apart. Two separate forces are thought to be responsible for anaphase B. The elongation and sliding of the overlap microtubules past one another in the central spindle push the two poles apart, and outward forces exerted by the astral microtubules at each spindle pole act to pull the poles away from each other, toward the cell surface.

Molecular Biology of the Cell ➔ IV. Internal Organization of the Cell ➔ 18. The Mechanics of Cell Division ➔ Mitosis

Figure 18-27. Two alternative models of how the kinetochore may generate a poleward force on its chromosome during anaphase A. (A) Microtubule motor proteins at the kinetochore use the energy of ATP hydrolysis to pull the chromosome along its bound microtubules. Depolymerization of the kinetochore microtubules follows as a consequence. (B) Chromosome movement is driven by kinetochore microtubule disassembly: as tubulin subunits dissociate, the kinetochore is obliged to slide poleward to maintain its binding to the walls of the microtubule. As motor proteins are required for anaphase A, in this model, they would be required mainly for the microtubules to remain attached to the kinetochore.

Cytokinesis

The cell cycle culminates in the division of the cytoplasm by **cytokinesis**. In a typical cell, cytokinesis accompanies every mitosis, although some cells, such as *Drosophila* embryos (discussed later) and vertebrate osteoclasts (discussed in [Chapter 22](#)), undergo mitosis without cytokinesis and become multinucleate. Cytokinesis begins in anaphase and ends in telophase, reaching completion as the next interphase begins.

The first visible change of cytokinesis in an animal cell is the sudden appearance of a pucker, or *cleavage furrow*, on the cell surface. The furrow rapidly deepens and spreads around the cell until it completely divides the cell in two. In animal cells and many unicellular eucaryotes, the structure that accomplishes cytokinesis is the *contractile ring*—a dynamic assembly composed of actin filaments, myosin II filaments, and many structural and regulatory proteins. The ring assembles just beneath the plasma membrane and contracts to constrict the cell into two (see [Figure 18-4](#)). At the same time, new membrane is inserted into the plasma membrane adjacent to the contractile ring by the fusion of intracellular vesicles. This addition of membrane is required to compensate for the increase in surface area that accompanies cytoplasmic division. Thus, cytokinesis can be considered to occur in four stages—initiation, contraction, membrane insertion, and completion.

The central problem for a cell undergoing cytokinesis is to ensure that it occurs at the right time and in the right place. Cytokinesis must not occur too early in M-phase, or it will disrupt the path of the separating chromosomes. It must also occur at the right place to separate the two segregating sets of chromosomes properly so that each daughter cell receives a complete set.

The Microtubules of the Mitotic Spindle Determine the Plane of Animal Cell Division

The mitotic spindle in animal cells not only separates the daughter chromosomes, it also specifies the location of the contractile ring, and thereby the plane of cell division. The contractile ring invariably forms in the plane of the metaphase plate, at right angles to the long axis of the mitotic spindle,

[Figure 18-37.](#)

[Figure 18-40. The](#)

[FtsZ protein.](#)

[Figure 18-41. The](#)

[use of different chromosome...](#)

thereby ensuring that division occurs between the two sets of separated chromosomes. The part of the spindle that specifies the division plane varies depending on the cell type: in some cells, it is the astral microtubules; in others, it is the overlapping antiparallel microtubules in the central spindle.

The relationship between the spindle microtubules and the placement of the contractile ring has been studied by manipulating fertilized eggs of marine invertebrates. After fertilization, these embryos undergo a series of rapid cleavage divisions, without intervening periods of growth. In this way, the original egg is progressively divided up into smaller and smaller cells. During cytokinesis, the cleavage furrow appears suddenly on the surface of the cell and deepens rapidly ([Figure 18-30](#)). Because the cytoplasm is clear, the spindle can be observed in real time through a microscope. If the spindle is tugged into a new position with a fine glass needle in early anaphase, the incipient cleavage furrow disappears, and a new one develops in accord with the new spindle site.

How does the mitotic spindle control the plane of division? Ingenious experiments in large embryonic cells demonstrate that a cleavage furrow forms midway between the asters originating from the two centrosomes, even when the two centrosomes are not connected to each other by a mitotic spindle ([Figure 18-31](#)). Thus, in these cells, the microtubule asters—not the chromosomes or other parts of the spindle—signal to the cell cortex to specify where the contractile ring should assemble. In other cells, the central spindle, rather than the astral microtubules, is apparently responsible for this specification. In either case, it has been speculated that the overlapping microtubules may provide tracks for motor proteins to deliver contractile ring regulators, and perhaps new membrane, to the appropriate region of the dividing cell. But, in fact, the molecular mechanism by which the spindle positions the cleavage furrow remains a mystery.

In some cells, the site of ring assembly is chosen before mitosis, according to a landmark placed in the cortex during a previous cell cycle. In budding yeasts, for example, a ring of proteins called *septins* assembles before mitosis, adjacent to a bud scar left on the cell surface as the mother and daughter cells separated in the previous division. The septins are thought to form a scaffold onto which other components of the contractile ring, including myosin II, assemble. As we discuss later, in plant cells, an organized band of microtubules and actin filaments assembles just before mitosis and marks the site where the cell wall will assemble and divide the cell in two. [↑ TOP](#)

Some Cells Reposition Their Spindle to Divide Asymmetrically

Most cells divide symmetrically. In most animal cells, for example, the contractile ring forms around the equator of the parent cell, so that the two daughter cells produced are of equal size and have similar properties. This

symmetry results from the placement of the mitotic spindle, which in most cases tends to center itself in the cytoplasm. The centering process depends both on astral microtubules and on motor proteins that either push or pull on the astral microtubules to center the spindle.

There are many instances in development, however, when cells divide asymmetrically to produce two cells that differ in size, in the cytoplasmic contents they inherit, or in both. Usually, the two daughter cells are destined to develop along different pathways. To create daughter cells with different fates, the mother cell must first segregate some components (called *fate determinants*) to one side of the cell and then position the plane of division so that the appropriate daughter cell inherits these components ([Figure 18-32](#)). To position the plane of division asymmetrically, the spindle has to be moved in a controlled manner within the dividing cell. It seems likely that such spindle movements are directed by changes in local regions of the cell cortex and that motor proteins localized there pull one of the spindle poles, via its astral microtubules, to the appropriate region ([Figure 18-33](#)). Some of the proteins required for such asymmetrical divisions have been identified through genetic analyses in *C. elegans* and *Drosophila* (discussed in [Chapter 21](#)), and some of these seem to have a similar role in vertebrates.

Asymmetric division is particularly important in plant cells. As these cells cannot move after division, the selection of division planes is crucial for controlling tissue morphology. We discuss later how the plane of division is determined in these cells. [↑ TOP](#)

Actin and Myosin II in the Contractile Ring Generate the Force for Cytokinesis

As the astral microtubules in anaphase become longer lived and less dynamic in response to the loss of M-Cdk activity, the contractile ring begins to assemble beneath the plasma membrane. Much of the preparation for cytokinesis, however, happens earlier in mitosis, before the division of the cytoplasm actually begins. In interphase cells, actin and myosin filaments are assembled into a cortical network and, in some cells, also into large cytoplasmic bundles called *stress fibers* (discussed in [Chapter 16](#)). As cells enter mitosis, these arrays disassemble; much of the actin is reorganized, and myosin II filaments are released. As the chromatids separate in anaphase, myosin II begins to accumulate in the rapidly assembling contractile ring ([Figure 18-34](#)).

In many cells, cytokinesis requires the activation of one or more members of the **polo-like family** of protein kinases. These kinases regulate the assembly of both the mitotic spindle and the contractile ring and are therefore thought to help coordinate mitosis and cytokinesis, but it is uncertain how they do so. The fully assembled contractile ring contains many proteins in addition to actin and myosin II. The overlapping arrays of actin filaments and bipolar myosin II

filaments, however, generate the force that divides the cytoplasm in two. They are thought to contract by a mechanism that is biochemically similar to that used by smooth muscle cells; in both cases, for example, the contraction begins when Ca^{2+} -calmodulin activates myosin light-chain kinase to phosphorylate myosin II. Once contraction has been stimulated, the ring develops a force large enough to bend a fine glass needle that is inserted in the path of the constricting ring.

How the contractile ring constricts is still a mystery. It seems not to operate by a simple "purse-string" mechanism, with actin and myosin II filaments sliding past each other as in skeletal muscle (see [Figure 16-71](#)). As the ring constricts, the ring maintains the same thickness in cross-section, suggesting that its total volume and the number of filaments it contains decrease steadily. Moreover, unlike in muscle, the actin filaments in the ring are highly dynamic, and their arrangement changes extensively during cytokinesis.

In addition to specifying the site of contractile ring assembly in early anaphase, in many cells, microtubules also work continuously during anaphase and telophase to stabilize the advancing cleavage furrow. Drugs that depolymerize microtubules, for example, cause the actin filaments in the contractile ring to become less organized. Moreover, if a needle is used to tear microtubules away from the cell cortex, the contractile ring disassembles and the cleavage furrow regresses. It is not known how the microtubules stabilize the ring, although it has been shown that growing microtubules can activate some members of the Rho family of small GTPases, which in turn stimulate actin polymerization (discussed in [Chapter 16](#)). One member of this family, Rho A, is required for cytokinesis.

The contractile ring is finally dispensed with altogether when cleavage ends, as the plasma membrane of the cleavage furrow narrows to form the midbody. The midbody persists as a tether between the two daughter cells and contains the remains of the central spindle, which now consists of the two sets of antiparallel overlap microtubules packed tightly together within a dense matrix material ([Figure 18-35](#)). Remarkably, in some cells, before cytokinesis has been completed, the mother centriole from one or both daughter cells separates from its daughter centriole (see [Figure 18-5c](#)) and migrates into the midbody, where it lingers for minutes, before returning to its daughter cell. Only then do the two daughter cells separate to complete cytokinesis. What the centriole might do in the midbody to trigger the final steps of cytokinesis is not known. After the daughter cells separate completely, some of the components of the residual midbody often remain on the inside of the plasma membrane of each cell, where they may serve as a mark on the cortex that helps to orient the spindle in the subsequent cell division.  [TOP](#)

Membrane-enclosed Organelles Must Be Distributed to Daughter Cells During Cytokinesis

The process of mitosis ensures that each daughter cell receives a full complement of chromosomes. But when a eucaryotic cell divides, each daughter cell must also inherit all of the other essential cell components, including the membrane-enclosed organelles. As discussed in [Chapter 12](#), organelles like mitochondria and chloroplasts cannot assemble spontaneously from their individual components; they can arise only from the growth and division of the preexisting organelles. Similarly, cells cannot make a new endoplasmic reticulum (ER) unless some part of it is already present.

How, then, are the various membrane-enclosed organelles segregated when a cell divides? Organelles such as mitochondria and chloroplasts are usually present in large enough numbers to be safely inherited if, on average, their numbers roughly double once each cycle. The ER in interphase cells is continuous with the nuclear membrane and is organized by the microtubule cytoskeleton. Upon entry into M phase, the reorganization of the microtubules releases the ER, which fragments as the nuclear envelope breaks down. The Golgi apparatus probably fragments as well, although in some cells it seems to redistribute transiently into the ER, only to re-emerge at telophase. Some of the organelle fragments associate with the spindle microtubules via motor proteins, thereby hitching a ride into the daughter cells as the spindle elongates in anaphase. [↑ TOP](#)

Mitosis Can Occur Without Cytokinesis

Although nuclear division is usually followed by cytoplasmic division, there are exceptions. Some cells undergo multiple rounds of nuclear division without intervening cytoplasmic division. In the early *Drosophila* embryo, for example, the first 13 rounds of nuclear division occur without cytoplasmic division, resulting in the formation of a single large cell containing 6000 nuclei, arranged in a monolayer near the surface ([Figure 18-36](#)). This arrangement greatly speeds up early development, as the cells do not have to take the time to go through all the steps of cytokinesis for each division. After these rapid nuclear divisions, cells are created around each nucleus in one round of coordinated cytokinesis called [cellularization](#). Contractile rings form at the cell surface, and the plasma membrane extends inward and pinches off to enclose each nucleus.

Nuclear division without cytokinesis also occurs in some types of mammalian cells. Osteoclasts, trophoblasts, and some hepatocytes and heart muscle cells, for example, become multinucleated in this way. [↑ TOP](#)

The Phragmoplast Guides Cytokinesis in Higher Plants

Most higher-plant cells are enclosed by a semirigid *cell wall*, and their mechanism of cytokinesis is different from that just described for animal cells. Rather than a contractile ring dividing the cytoplasm from the outside in, the cytoplasm of the plant cell is partitioned from the inside out by the

construction of a new cell wall, called the cell plate, between the two daughter nuclei (Figure 18-37). The orientation of the cell plate determines the positions of the two daughter cells relative to neighboring cells. It follows that altering the planes of cell division, together with enlargement of the cells by expansion or growth, leads to different cell and tissue shapes that help determine the form of the plant.

The mitotic spindle by itself is not sufficient to determine the exact position and orientation of the cell plate. The first visible sign that a higher-plant cell has become committed to divide in a particular plane is seen in G_2 , when the cortical array of microtubules disappears in preparation for mitosis. At this time, a circumferential band of microtubules and actin filaments forms a ring around the entire cell just beneath the plasma membrane. Because this cytoskeletal array appears before prophase begins, it is called the preprophase band. The band becomes thinner as the cell progresses to prophase, and it disappears completely before metaphase is reached. Yet, the division plane has somehow been established: when the new cell plate forms later during cytokinesis, it grows outward to fuse with the parental wall precisely at the zone formerly occupied by the preprophase band. Even if the cell contents are displaced by centrifugation after the preprophase band has disappeared, the growing cell plate tends to find its way back to the plane defined by the former preprophase band.

The assembly of the cell plate begins in late anaphase and is guided by a structure called the phragmoplast, which contains the remaining overlap microtubules of the mitotic spindle that interdigitate at their growing plus ends. This region of overlap is similar in structure to the central spindle in animal cells in late anaphase. Small vesicles, largely derived from the Golgi apparatus and filled with polysaccharide and glycoproteins required for the synthesis of the new cell-wall matrix, are transported along the microtubules to the equator of the phragmoplast, apparently by the action of microtubule-dependent motor proteins. Here, the vesicles fuse to form a disclike, membrane-enclosed structure called the *early cell plate* (see Figure 18-9G). The plate expands outward by further vesicle fusion until it reaches the plasma membrane and the original cell wall and divides the cell in two. Later, cellulose microfibrils are laid down within the matrix of the cell plate to complete the construction of the new cell wall (Figure 18-38). [↑ TOP](#)

The Elaborate M Phase of Higher Organisms Evolved Gradually from Procaryotic Fission Mechanisms

Procaryotic cells divide by a process called **binary fission**. The single, circular DNA molecule replicates and division occurs by the invagination of the plasma membrane and the laying down of new cell wall between the two chromosomes to produce two separate daughter cells. In *E. coli*, before the chromosome replicates, the single origin of replication (*oriC*) is located at one

pole of the rod-shaped bacterium. As soon as *oriC* is replicated, one copy of the sequence is immediately translocated to the opposite pole of the cell, after which the rest of the chromosome is replicated. Like the two spindle-pole asters in an animal cell, the bacterial daughter chromosomes at the cell poles somehow determine the location of the plane of cell division, ensuring that fission takes place at the cell equator, so that each daughter cell inherits one chromosome (Figure 18-39). Although a number of genes and proteins involved have been identified, the mechanisms responsible for the active translocation of *oriC* and the inhibition of fission everywhere but at the equator remain unknown.

Binary fission in procaryotes depends on filaments made of the **FtsZ protein**. FtsZ is a cytoskeletal GTPase that is structurally related to tubulin and assembles into a ring at the equator of the cell (Figure 18-40A, and see Figure 16-17). The FtsZ filaments are essential for the recruitment of all the other cell division proteins to the division site. Together, these proteins guide the inward growth of the cell wall and membrane, leading to the formation of a septum that divides the cell into two. Bacteria in which the *ftsZ* gene is inactivated by mutation cannot divide. A FtsZ-based mechanism is also used in the division of chloroplasts in plant cells (Figure 18-40B) and mitochondria in protists. In fungi and animal cells, another self-assembling GTPase called *dynamitin* (discussed in Chapter 13) has apparently taken over the function of FtsZ in mitochondrial division.

With the evolution of the eucaryotes, the genome increased in complexity, and the chromosomes increased in both number and size. For these organisms, a more elaborate mechanism for dividing the chromosomes between daughter cells was apparently required. Clearly, the mitotic apparatus could not have evolved all at once. In many primitive eucaryotes, such as the dinoflagellate *Cryptothecodinium cohnii*, mitosis depends on a membrane-attachment mechanism, in which the chromosomes have to bind to the inner nuclear membrane for segregation. The intermediate status of this large, single-celled alga is reflected in the composition of its chromosomes, which, like those of procaryotes, have relatively little associated protein. The nuclear membrane in *C. cohnii* remains intact throughout mitosis, and the spindle microtubules remain entirely outside the nucleus. Where these spindle microtubules press on the outside of the nuclear envelope, the envelope becomes indented in a series of parallel channels (Figure 18-41). The chromosomes become attached to the inner membrane of the nuclear envelope opposite these channels, and chromosome segregation occurs on the inside of this channeled nuclear membrane. Thus, the extranuclear "spindle" is used to order the nuclear membrane and thereby define the plane of division. Kinetochores in this species seem to be integrated into the nuclear membrane and may therefore have evolved from some membrane component.

Eucaryotic tubulin and procaryotic FtsZ clearly have a common evolutionary history. But, microtubules are important for chromosome segregation in even

the most primitive eucaryotes, where they are also present in flagellar axonemes (discussed in [Chapter 16](#)). Whether the flagellum or the spindle evolved first is unclear.

A somewhat more advanced, although still extranuclear, spindle is seen in *hypermastigotes*, in which the nuclear envelope again remains intact throughout mitosis. These large protozoa from the guts of insects provide a particularly clear illustration of the independence of spindle elongation and the chromosome movements that separate the chromatids. The sister kinetochores become separated by the growth of the nuclear membrane (to which they are attached) before becoming attached to the spindle. Only when the kinetochores are near the poles of the spindle do they acquire the kinetochore microtubules needed to attach them to the spindle. Because the spindle microtubules remain separated from the chromosomes by the nuclear envelope, the kinetochore microtubules, which are formed outside the nucleus, must somehow attach to the chromosomes through the nuclear membranes. After this attachment has occurred, the kinetochores are drawn poleward in a conventional manner (see [Figure 18-41](#)).

Organisms that form spindles inside an intact nucleus may represent a further stage in the evolution of mitotic mechanisms. In both yeasts and diatoms, the spindle is attached to chromosomes by their kinetochores, and the chromosomes are segregated in a way loosely similar to that described for animal cells—except that the entire process generally occurs within the confines of the nuclear envelope (see [Figure 18-41](#)). It is thought that the "open" mitosis of higher organisms and the "closed" mitosis of yeasts and diatoms evolved separately from a common ancestor resembling the modern hypermastigote spindle. At present, there is no convincing explanation for why higher plants and animals have evolved a mitotic apparatus that requires the controlled and reversible dissolution of the nuclear envelope. [↑ TOP](#)

Summary

Cell division ends as the cytoplasm divides into two by the process of cytokinesis. Except for plants, cytokinesis in eucaryotic cells is mediated by a contractile ring, which is composed of actin and myosin filaments and a variety of other proteins. By an unknown mechanism, the mitotic spindle determines when and where the contractile ring assembles and, thereby, when and where the cell divides. Most cells divide symmetrically to produce two cells of the same content and size. Some cells, however, specifically position their spindle to divide asymmetrically, producing two daughter cells that differ in size, content, or both. Cytokinesis occurs by a special mechanism in higher-plant cells—in which the cytoplasm is partitioned by the construction of a new cell wall, the cell plate, inside the cell. The position of the cell plate is determined by the position of a preprophase band of microtubules and actin filaments. The organization of mitosis in fungi and some protozoa differs from that in animals and plants, suggesting how the complex process of eucaryotic

cell division may have evolved. [↑ TOP](#)

Figure 18-31. An experiment demonstrating the influence of the position of microtubule asters on the subsequent plane of cleavage in a large egg cell.

If the mitotic spindle is mechanically pushed to one side of the cell with a glass bead, the membrane furrowing is incomplete, failing to occur on the opposite side of the cell. Subsequent cleavages occur not only in the conventional relation to each of the two subsequent mitotic spindles (*yellow arrowheads*), but also between the two adjacent asters that are not linked by a mitotic spindle—but in this abnormal cell share the same cytoplasm (*red arrowhead*). Apparently, the contractile ring that produces the cleavage furrow in these cells always forms in the region midway between two asters, suggesting that the asters somehow alter the adjacent region of cell cortex to induce furrow formation between them.

Figure 18-32. An asymmetric cell division segregating cytoplasmic components to only one daughter cell. These light micrographs illustrate the controlled asymmetric segregation of specific cytoplasmic components to one daughter cell during the first division of a fertilized egg of the nematode *C. elegans*. The cells *above* have been stained with a *blue*, DNA-binding, fluorescent dye to show the nucleus (and polar bodies—see [Figure 20-22](#)); they are viewed by both differential-interference-contrast and fluorescence microscopy. The cells *below* are the same cells stained with an antibody against P-granules and viewed by fluorescence microscopy. These small granules of unknown function are distributed randomly throughout the cytoplasm of the unfertilized egg (not shown) but become segregated to the posterior pole of the fertilized egg, as shown on the *left*. The cleavage plane is oriented to ensure that only the posterior daughter cell receives the P-granules when the egg divides, as shown on the *right*. The same segregation process is repeated in several subsequent cell divisions, so that the P-granules end up only in the cells that give rise to eggs and sperm. (Courtesy of Susan Strome.)

Figure 18-38. The special features of cytokinesis in a higher plant cell. The division plane is established before M phase by a band of microtubules and actin filaments (the preprophase band) at the cell cortex. At the beginning of telophase, after the chromosomes have segregated, a new cell wall starts to assemble inside the cell at the equator of the old spindle. The overlap microtubules of the mitotic spindle remaining at telophase form the phragmoplast and guide vesicles derived from the Golgi apparatus toward the center of the spindle. The vesicles are filled with cell-wall material and fuse to form the growing new cell wall, which grows outward to reach the plasma membrane and original cell wall at the site determined earlier by the preprophase band. The plasma membrane and the membrane surrounding the new cell wall fuse, completely separating the two daughter cells.

V. Cells in Their Social Context

Multicellular organisms start life as a fertilized egg cell. In this egg chamber of the fly *Drosophila*, the outlines of the component cells are revealed by the actin (stained *red*) that underlies their plasma membranes. The large cell at the bottom is the egg cell, which contains an asymmetrically localized protein called Staufen (*green*). Surrounding the egg cell is a row of follicle cells and at the top is a group of large nurse cells. (Courtesy of Daniel St Johnston.)

Molecular Biology of the Cell → V. Cells in Their Social Context

19. Cell Junctions, Cell Adhesion, and the Extracellular Matrix

In this chapter, we consider what holds the cells of a multicellular organism together. Cells are small, deformable, and often motile objects, filled with an aqueous medium and enclosed in a flimsy plasma membrane; yet they can combine in their millions to form a structure as massive, as strong, and as strictly ordered as a horse or a tree. We have to explain what gives such multicellular assemblies their strength and keeps the cells in their proper places.

The building technologies of animals and plants are different, and each type of organism is formed of many types of *tissues*, in which the cells are assembled and bound together in different ways. In both animals and plants, however, an essential part is played in most tissues by the *extracellular matrix*. This complex network of secreted extracellular macromolecules has many functions, but first and foremost it forms a supporting framework. It helps hold cells and tissues together, and, in animals, it provides an organized environment within which migratory cells can move and interact with one another in orderly ways. The extracellular matrix, however, is only half the story. In animals especially, the cells of most tissues are bound directly to one another by *cell-cell junctions*. These too are of many types, serving many purposes in addition to mechanical attachment; but without them, our bodies would disintegrate.

In vertebrates, the major tissue types are nerve, muscle, blood, lymphoid, epithelial, and connective tissues. Connective tissue and epithelial tissue represent two extremes of organization ([Figure 19-1](#)). In [connective tissue](#), the extracellular matrix is plentiful, and cells are sparsely distributed within it. The matrix is rich in fibrous polymers, especially *collagen*, and it is the matrix—rather than the cells—that bears most of the mechanical stress to which the tissue is subjected. Direct attachments between one cell and another are relatively rare.

In **epithelial tissue**, by contrast, cells are tightly bound together into sheets called **epithelia**. The extracellular matrix is scanty, consisting mainly of a thin mat called the *basal lamina*, which underlies the epithelium. The cells are attached to each other by cell-cell adhesions, which bear most of the

mechanical stresses. For this purpose, strong intracellular protein filaments (components of the cytoskeleton) cross the cytoplasm of each epithelial cell and attach to specialized junctions in the plasma membrane. The junctions, in turn, tie the surfaces of adjacent cells either to each other or to the underlying basal lamina.

Epithelial cell sheets line all the cavities and free surfaces of the body. The specialized junctions between the cells enable epithelia to form barriers that inhibit the movement of water, solutes, and cells from one body compartment to another. As illustrated in [Figure 19-1](#), epithelia almost always rest on a supporting bed of connective tissue. This supporting bed may in turn attach them to other tissues, such as the muscle shown in the figure. In this way, tissues join together in various combinations to form larger functional units called *organs*.

In this chapter, we first discuss the structure and function of the specialized cell-cell and cell-matrix junctions, which are collectively called *cell junctions*. We next consider how animal cells recognize and bind to one another as they move and assemble into tissues and organs—a process called *cell adhesion*. We then discuss the structure and organization of the extracellular matrix in animals, as well as the main cell-surface receptors that animal cells use to bind to the matrix. Finally, we consider the special extracellular matrix that surrounds each cell in a plant—the plant cell wall.

Cell Junctions

Specialized cell junctions occur at points of cell-cell and cell-matrix contact in all tissues, and they are particularly plentiful in epithelia. Cell junctions are best visualized using either conventional or freeze-fracture electron microscopy (discussed in Chapter 9), which reveals that the interacting plasma membranes (and often the underlying cytoplasm and the intervening intercellular space as well) are highly specialized in these regions.

Cell junctions can be classified into three functional groups:

1. Occluding junctions seal cells together in an epithelium in a way that prevents even small molecules from leaking from one side of the sheet to the other.
2. Anchoring junctions mechanically attach cells (and their cytoskeletons) to their neighbors or to the extracellular matrix.
3. Communicating junctions mediate the passage of chemical or electrical signals from one interacting cell to its partner.

The major kinds of intercellular junctions within each group are listed in Table 19-1. We discuss each of them in turn, except for chemical synapses, which are formed exclusively by nerve cells and are considered in Chapters 11 and 15.

Occluding Junctions Form a Selective Permeability Barrier Across Epithelial Cell Sheets

All epithelia have at least one important function in common: they serve as selective permeability barriers, separating fluids on either side that have a different chemical composition. This function requires that the adjacent cells be sealed together by occluding junctions. Tight junctions have this barrier role in vertebrates, as we illustrate by considering the epithelium of the mammalian small intestine, or gut.

Tables

 [Table 19-1. A Functional Classification of Cell...](#)

 [Table 19-2. Anchoring Junctions](#)

The epithelial cells lining the small intestine form a barrier that keeps the gut contents in the gut cavity, the *lumen*. At the same time, however, the cells must transport selected nutrients across the epithelium from the lumen into the extracellular fluid that permeates the connective tissue on the other side (see [Figure 19-1](#)). From there, these nutrients diffuse into small blood vessels to provide nourishment to the organism. This *transcellular transport* depends on two sets of membrane-bound transport proteins. One set is confined to the *apical surface* of the epithelial cell (the surface facing the lumen) and actively transports selected molecules into the cell from the gut. The other set is confined to the *basolateral* (basal and lateral) *surfaces* of the cell, and it allows the same molecules to leave the cell by facilitated diffusion into the extracellular fluid on the other side of the epithelium. To maintain this directional transport, the apical set of transport proteins must not be allowed to migrate to the basolateral surface of the cell, and the basolateral set must not be allowed to migrate to the apical surface. Furthermore, the spaces between epithelial cells must be tightly sealed, so that the transported molecules cannot diffuse back into the gut lumen through these spaces ([Figure 19-2](#)).

The tight junctions between epithelial cells are thought to have both of these roles. First, they function as barriers to the diffusion of some membrane proteins (and lipids) between apical and basolateral domains of the plasma membrane (see [Figure 19-2](#)). Mixing of such proteins and lipids occurs if tight junctions are disrupted, for example, by removing the extracellular Ca^{2+} that is required for tight junction integrity. Second, tight junctions seal neighboring cells together so that, if a low-molecular-weight tracer is added to one side of an epithelium, it will generally not pass beyond the tight junction ([Figure 19-3](#)). This seal is not absolute, however. Although all tight junctions are impermeable to macromolecules, their permeability to small molecules varies greatly in different epithelia. Tight junctions in the epithelium lining the small intestine, for example, are 10,000 times more permeable to inorganic ions, such as Na^+ , than the tight junctions in the epithelium lining the urinary bladder. These differences reflect differences in tight junction proteins that form the junctions.

Epithelial cells can transiently alter their tight junctions to permit an increased flow of solutes and water through breaches in the junctional barriers. Such *paracellular transport* is especially important in the absorption of amino acids and monosaccharides from the lumen of the intestine, where their concentration can increase enough after a meal to drive passive transport in the desired direction.

When tight junctions are visualized by freeze-fracture electron microscopy, they seem to be composed of a branching network of *sealing strands* that completely encircles the apical end of each cell in the epithelial sheet ([Figure 19-4A and B](#)). In conventional electron micrographs, the outer leaflets of the two interacting plasma membranes are seen to be tightly apposed where sealing strands are present ([Figure 19-4C](#)). The ability of tight junctions to

Search

This book
books

All

PubMed

restrict the passage of ions through the spaces between cells is found to increase logarithmically with increasing numbers of strands in the network, suggesting that each strand acts as an independent barrier to ion flow.

Each tight junction sealing strand is composed of a long row of transmembrane adhesion proteins embedded in each of the two interacting plasma membranes. The extracellular domains of these proteins join directly to one another to occlude the intercellular space (Figure 19-5). The major transmembrane proteins in a tight junction are the *claudins*, which are essential for tight junction formation and function and differ in different tight junctions. A specific claudin found in kidney epithelial cells, for example, is required for Mg^{2+} to be resorbed from the urine into the blood. A mutation in the gene encoding this claudin results in excessive loss of Mg^{2+} in the urine. A second major transmembrane protein in tight junctions is *occludin*, the function of which is uncertain. Claudins and occludins associate with intracellular peripheral membrane proteins called *ZO proteins* (a tight junction is also known as a *zonula occludens*), which anchor the strands to the actin cytoskeleton.

In addition to claudins, occludins, and ZO proteins, several other proteins can be found associated with tight junctions. These include some that regulate epithelial cell polarity and others that help guide the delivery of components to the appropriate domain of the plasma membrane. Thus, the tight junction may serve as a regulatory center to help in coordinating multiple cell processes.

In invertebrates, septate junctions are the main occluding junction. More regular in structure than a tight junction, they likewise form a continuous band around each epithelial cell. But their morphology is distinct because the interacting plasma membranes are joined by proteins that are arranged in parallel rows with a regular periodicity (Figure 19-6). A protein called *Discs-large*, which is required for the formation of septate junctions in *Drosophila*, is structurally related to the ZO proteins found in vertebrate tight junctions. Mutant flies that are deficient in this protein not only lack septate junctions but also develop epithelial tumors. This observation suggests that the normal regulation of cell proliferation in epithelial tissues may depend, in part, on intracellular signals that emanate from occluding junctions. [↑ TOP](#)

Anchoring Junctions Connect the Cytoskeleton of a Cell Either to the Cytoskeleton of Its Neighbors or to the Extracellular Matrix

The lipid bilayer is flimsy and cannot by itself transmit large forces from cell to cell or from cell to extracellular matrix. Anchoring junctions solve the problem by forming a strong membrane-spanning structure that is tethered inside the cell to the tension-bearing filaments of the cytoskeleton (Figure 19-7).

Anchoring junctions are widely distributed in animal tissues and are most abundant in tissues that are subjected to severe mechanical stress, such as heart, muscle, and epidermis. They are composed of two main classes of proteins ([Figure 19-8](#)). *Intracellular anchor proteins* form a distinct plaque on the cytoplasmic face of the plasma membrane and connect the junctional complex to either actin filaments or intermediate filaments. *Transmembrane adhesion proteins* have a cytoplasmic tail that binds to one or more intracellular anchor proteins and an extracellular domain that interacts with either the extracellular matrix or the extracellular domains of specific transmembrane adhesion proteins on another cell. In addition to anchor proteins and adhesion proteins, many anchoring junctions contain intracellular signaling proteins that enable the junctions to signal to the cell interior.

Anchoring junctions occur in two functionally different forms:

1. Adherens junctions and desmosomes hold cells together and are formed by transmembrane adhesion proteins that belong to the *cadherin family*.
2. Focal adhesions and hemidesmosomes bind cells to the extracellular matrix and are formed by transmembrane adhesion proteins of the *integrin family*.

On the intracellular side of the membrane, adherens junctions and focal adhesions serve as connection sites for actin filaments, while desmosomes and hemidesmosomes serve as connection sites for intermediate filaments (see [Table 19-1](#), p. 1067). [↑ TOP](#)

Adherens Junctions Connect Bundles of Actin Filaments from Cell to Cell

Adherens junctions occur in various forms. In many nonepithelial tissues, they take the form of small punctate or streaklike attachments that indirectly connect the cortical actin filaments beneath the plasma membranes of two interacting cells. But the prototypical examples of adherens junctions occur in epithelia, where they often form a continuous adhesion belt (or *zonula adherens*) just below the tight junctions, encircling each of the interacting cells in the sheet. The adhesion belts are directly apposed in adjacent epithelial cells, with the interacting plasma membranes held together by the cadherins that serve here as transmembrane adhesion proteins.

Within each cell, a contractile bundle of actin filaments lies adjacent to the adhesion belt, oriented parallel to the plasma membrane. The actin is attached to this membrane through a set of intracellular anchor proteins, including *catenins*, *vinculin*, and *α-actinin*, which we consider later. The actin bundles are thus linked, via the cadherins and anchor proteins, into an extensive transcellular network ([Figure 19-9](#)). This network can contract with the help of

myosin motor proteins (discussed in [Chapter 16](#)), and it is thought to help in mediating a fundamental process in animal morphogenesis—the folding of epithelial cell sheets into tubes and other related structures ([Figure 19-10](#)).

The assembly of tight junctions between epithelial cells seems to require the prior formation of adherens junctions. Anti-cadherin antibodies that block the formation of adherens junctions, for example, also block the formation of tight junctions. [↑ TOP](#)

Desmosomes Connect Intermediate Filaments from Cell to Cell

Desmosomes are buttonlike points of intercellular contact that rivet cells together ([Figure 19-11A](#)). Inside the cell, they serve as anchoring sites for ropelike intermediate filaments, which form a structural framework of great tensile strength ([Figure 19-11B](#)). Through desmosomes, the intermediate filaments of adjacent cells are linked into a net that extends throughout the many cells of a tissue. The particular type of intermediate filaments attached to the desmosomes depends on the cell type: they are *keratin filaments* in most epithelial cells, for example, and *desmin filaments* in heart muscle cells.

The general structure of a desmosome is illustrated in [Figure 19-11C](#), and some of the proteins that form it are shown in [Figure 19-11D](#). The junction has a dense cytoplasmic plaque composed of a complex of intracellular anchor proteins (*plakoglobin* and *desmoplakin*) that are responsible for connecting the cytoskeleton to the transmembrane adhesion proteins. These adhesion proteins (*desmoglein* and *desmocollin*), like those at an adherens junction, belong to the cadherin family. They interact through their extracellular domains to hold the adjacent plasma membranes together.

The importance of desmosome junctions is demonstrated by some forms of the potentially fatal skin disease *pemphigus*. Affected individuals make antibodies against one of their own desmosomal cadherin proteins. These antibodies bind to and disrupt the desmosomes that hold their skin epithelial cells (keratinocytes) together. This results in a severe blistering of the skin, with leakage of body fluids into the loosened epithelium. [↑ TOP](#)

Anchoring Junctions Formed by Integrins Bind Cells to the Extracellular Matrix: Focal Adhesions and Hemidesmosomes

Some anchoring junctions bind cells to the extracellular matrix rather than to other cells. The transmembrane adhesion proteins in these cell-matrix junctions are *integrins*—a large family of proteins distinct from the cadherins. **Focal adhesions** enable cells to get a hold on the extracellular matrix through

integrins that link intracellularly to actin filaments. In this way, muscle cells, for example, attach to their tendons at the *myotendinous junction*. Likewise, when cultured fibroblasts migrate on an artificial substratum coated with extracellular matrix molecules, they also grip the substratum at focal adhesions, where bundles of actin filaments terminate. At all such adhesions, the extracellular domains of transmembrane integrin proteins bind to a protein component of the extracellular matrix, while their intracellular domains bind indirectly to bundles of actin filaments via the intracellular anchor proteins talin, α -actinin, filamin, and vinculin (Figure 19-12B).

Hemidesmosomes, or half-desmosomes, resemble desmosomes morphologically and in connecting to intermediate filaments, and, like desmosomes, they act as rivets to distribute tensile or shearing forces through an epithelium. Instead of joining adjacent epithelial cells, however, hemidesmosomes connect the basal surface of an epithelial cell to the underlying basal lamina (Figure 19-13). The extracellular domains of the integrins that mediate the adhesion bind to a *laminin* protein (discussed later) in the basal lamina, while an intracellular domain binds via an anchor protein (*plectin*) to keratin intermediate filaments. Whereas the keratin filaments associated with desmosomes make lateral attachments to the desmosomal plaques (see Figure 19-11C and D), many keratin filaments associated with hemidesmosomes have their ends buried in the plaque (see Figure 19-13).

Although the terminology for the various anchoring junctions can be confusing, the molecular principles (for vertebrates, at least) are relatively simple (Table 19-2). Integrins in the plasma membrane anchor a cell to extracellular matrix molecules; cadherin family members in the plasma membrane anchor it to the plasma membrane of an adjacent cell. In both cases, there is an intracellular coupling to cytoskeletal filaments, either actin filaments or intermediate filaments, depending on the types of intracellular anchor proteins involved.

Gap Junctions Allow Small Molecules to Pass Directly from Cell to Cell

With the exception of a few terminally differentiated cells such as skeletal muscle cells and blood cells, most cells in animal tissues are in communication with their neighbors via gap junctions. Each gap junction appears in conventional electron micrographs as a patch where the membranes of two adjacent cells are separated by a uniform narrow gap of about 2–4 nm. The gap is spanned by channel-forming proteins (*connexins*). The channels they form (*connexons*) allow inorganic ions and other small water-soluble molecules to pass directly from the cytoplasm of one cell to the cytoplasm of the other, thereby coupling the cells both electrically and metabolically. Dye-injection experiments suggest a maximal functional pore size for the connecting channels of about 1.5 nm, implying that coupled cells share their small molecules (such as inorganic ions, sugars, amino acids, nucleotides,

vitamins, and the intracellular mediators cyclic AMP and inositol trisphosphate) but not their macromolecules (proteins, nucleic acids, and polysaccharides) (Figure 19-14). This cell coupling has important functional implications, many of which are only beginning to be understood.

Evidence that gap junctions mediate electrical and chemical coupling has come from many experiments. When, for example, connexin mRNA is injected into either frog oocytes or gap-junction-deficient cultured cells, channels with the properties expected of gap-junction channels can be demonstrated electrophysiologically where pairs of injected cells make contact.

The mRNA injection approach has been useful for identifying new gap-junction proteins. Genetic studies in the fruit fly *Drosophila* identified the gene *shaking B*, which, when mutated, resulted in flies that failed to jump in response to a visual stimulus. Although these flies had defective gap junctions, the sequence of the Shaking B protein did not resemble a connexin, and the function of the protein was unclear. An injection of the *shaking B* mRNA into frog oocytes, however, led to the formation of functional gap-junction channels, just like those formed by connexins. Shaking B thus became the first member of a new family of invertebrate gap-junction proteins called *innexins*. There are more than 15 *innexin* genes in *Drosophila* and 25 in the nematode *C. elegans*. [↑ TOP](#)

A Gap-Junction Connexon Is Made Up of Six Transmembrane Connexin Subunits

Connexins are four-pass transmembrane proteins, six of which assemble to form a channel, a connexon. When the connexons in the plasma membranes of two cells in contact are aligned, they form a continuous aqueous channel that connects the two cell interiors (Figure 19-15A). The connexons hold the interacting plasma membranes at a fixed distance apart—hence the gap.

Gap junctions in different tissues can have different properties. The permeability of their individual channels can vary, reflecting differences in the connexins that form the junctions. In humans, for instance, there are 14 distinct connexins, each encoded by a separate gene and each having a distinctive, but sometimes overlapping, tissue distribution. Most cell types express more than one type of connexin, and two different connexin proteins can assemble into a heteromeric connexon, the properties of which differ from those of a homomeric connexon constructed from a single type of connexin. Moreover, adjacent cells expressing different connexins can form intercellular channels in which the two aligned half-channels are different (Figure 19-15B). Each gap junction can contain a cluster of a few to many thousands of connexons (Figure 19-16B). [↑ TOP](#)

Gap Junctions Have Diverse Functions

In tissues containing electrically excitable cells, coupling via gap junctions serves an obvious purpose. Some nerve cells, for example, are electrically coupled, allowing action potentials to spread rapidly from cell to cell, without the delay that occurs at chemical synapses. This is advantageous when speed and reliability are crucial, as in certain escape responses in fish and insects. Similarly, in vertebrates, electrical coupling through gap junctions synchronizes the contractions of both heart muscle cells and the smooth muscle cells responsible for the peristaltic movements of the intestine.

Gap junctions also occur in many tissues that do not contain electrically excitable cells. In principle, the sharing of small metabolites and ions provides a mechanism for coordinating the activities of individual cells in such tissues and for smoothing out random fluctuations in small molecule concentrations in different cells. In the liver, for example, the release of noradrenaline from sympathetic nerve endings in response to a fall in blood glucose levels stimulates hepatocytes to increase glycogen breakdown and release glucose into the blood. Not all the hepatocytes are innervated by sympathetic nerves, however. By means of the gap junctions that connect hepatocytes, the signal is transmitted from the innervated hepatocytes to the noninnervated ones. Thus, mice with a mutation in the major connexin gene expressed in the liver fail to mobilize glucose normally when blood glucose levels fall.

The normal development of ovarian follicles also depends on gap-junction-mediated communication—in this case, between the oocyte and the surrounding granulosa cells. A mutation in the gene that encodes the connexin that normally couples these two cell types causes infertility ([Figure 19-17](#)).

Cell coupling via gap junctions also seems to be important in embryogenesis. In early vertebrate embryos, beginning with the late eight-cell stage in mouse embryos, most cells are electrically coupled to one another. As specific groups of cells in the embryo develop their distinct identities and begin to differentiate, they commonly uncouple from surrounding tissue. As the neural plate folds up and pinches off to form the neural tube, for instance (see [Figure 19-10](#)), its cells uncouple from the overlying ectoderm. Meanwhile, the cells within each group remain coupled with one another and therefore tend to behave as a cooperative assembly, all following a similar developmental pathway in a coordinated fashion. [↑ TOP](#)

The Permeability of Gap Junctions Can Be Regulated

Like conventional ion channels (discussed in [Chapter 11](#)), individual gap-junction channels do not remain continuously open; instead, they flip between open and closed states. Moreover, the permeability of gap junctions is rapidly (within seconds) and reversibly reduced by experimental manipulations that decrease the cytosolic pH or increase the cytosolic concentration of free Ca^{2+} to very high levels. Thus, gap-junction channels are dynamic structures that

can undergo a reversible conformational change that closes the channel in response to changes in the cell.

The purpose of the pH regulation of gap-junction permeability is unknown. In one case, however, the purpose of Ca^{2+} control seems clear. When a cell is damaged, its plasma membrane can become leaky. Ions present at high concentration in the extracellular fluid, such as Ca^{2+} and Na^+ , then move into the cell, and valuable metabolites leak out. If the cell were to remain coupled to its healthy neighbors, these too would suffer a dangerous disturbance of their internal chemistry. But the large influx of Ca^{2+} into the damaged cell causes its gap-junction channels to close immediately, effectively isolating the cell and preventing the damage from spreading to other cells.

Gap-junction communication can also be regulated by extracellular signals. The neurotransmitter *dopamine*, for example, reduces gap-junction communication between a class of neurons in the retina in response to an increase in light intensity (Figure 19-18). This reduction in gap-junction permeability helps the retina switch from using rod photoreceptors, which are good detectors of low light, to cone photoreceptors, which detect color and fine detail in bright light.

Figure 19-19 summarizes the various types of junctions formed by vertebrate cells in an epithelium. In the most apical portion of the cell, the relative positions of the junctions are the same in nearly all vertebrate epithelia. The tight junction occupies the most apical position, followed by the adherens junction (adhesion belt) and then by a special parallel row of desmosomes; together these form a structure called a *junctional complex*. Gap junctions and additional desmosomes are less regularly organized. [↑ TOP](#)

In Plants, Plasmodesmata Perform Many of the Same Functions as Gap Junctions

The tissues of a plant are organized on different principles from those of an animal. This is because plant cells are imprisoned within rigid *cell walls* composed of an extracellular matrix rich in cellulose and other polysaccharides, as we discuss later. The cell walls of adjacent cells are firmly cemented to those of their neighbors, which eliminates the need for anchoring junctions to hold the cells in place. But a need for direct cell-cell communication remains. Thus, plant cells have only one class of intercellular junctions, **plasmodesmata** (singular, plasmodesma). Like gap junctions, they directly connect the cytoplasm of adjacent cells.

In plants, however, the cell wall between a typical pair of adjacent cells is at least $0.1\ \mu\text{m}$ thick, and so a structure very different from a gap junction is required to mediate communication across it. Plasmodesmata solve the problem. With a few specialized exceptions, every living cell in a higher plant is connected to its living neighbors by these structures, which form fine

cytoplasmic channels through the intervening cell walls. As shown in [Figure 19-20A](#), the plasma membrane of one cell is continuous with that of its neighbor at each plasmodesma, and the cytoplasm of the two cells is connected by a roughly cylindrical channel with a diameter of 20–40 nm. Thus, the cells of a plant can be viewed as forming a syncytium, in which many cell nuclei share a common cytoplasm.

Running through the center of the channel in most plasmodesmata is a narrower cylindrical structure, the *desmotubule*, which is continuous with elements of the smooth endoplasmic reticulum in each of the connected cells ([Figures 19-20B](#) and [19-21A](#) and [B](#)). Between the outside of the desmotubule and the inner face of the cylindrical channel formed by plasma membrane is an annulus of cytosol through which small molecules can pass from cell to cell. As each new cell wall is assembled during the cytokinesis phase of cell division, plasmodesmata are created within it. They form around elements of smooth ER that become trapped across the developing cell plate (discussed in [Chapter 18](#)). They can also be inserted *de novo* through pre-existing cell walls, where they are commonly found in dense clusters called *pit fields* ([Figure 19-21C](#)). When no longer required, plasmodesmata can be readily removed.

In spite of the radical difference in structure between plasmodesmata and gap junctions, they seem to function in remarkably similar ways. Evidence obtained by injecting tracer molecules of different sizes suggests that plasmodesmata allow the passage of molecules with a molecular weight of less than about 800, which is similar to the molecular-weight cutoff for gap junctions. As with gap junctions, transport through plasmodesmata is regulated. Dye-injection experiments, for example, show that there can be barriers to the movement of even low-molecular-weight molecules between certain cells, or groups of cells, that are connected by apparently normal plasmodesmata; the mechanisms that restrict communication in these cases are not understood.

During plant development, groups of cells within the shoot and root meristems signal to one another in the process of defining their future fates (discussed in [Chapter 21](#)). Some gene regulatory proteins involved in this process of cell fate determination pass from cell to cell through plasmodesmata. They bind to components of the plasmodesmata and override the size exclusion mechanism that would otherwise prevent their passage. In some cases, the mRNA that encodes the protein can also pass through. Some plant viruses also exploit this route: infectious viral RNA, or even intact virus particles, can pass from cell to cell in this way. These viruses produce proteins that bind to components of the plasmodesmata to increase dramatically the effective pore size of the channel. As the functional components of plasmodesmata are unknown, it is unclear how endogenous or viral macromolecules regulate the transport properties of the channel to pass through it. [↑ TOP](#)

Summary

Many cells in tissues are linked to one another and to the extracellular matrix at specialized contact sites called cell junctions. Cell junctions fall into three functional classes: occluding junctions, anchoring junctions, and communicating junctions. Tight junctions are occluding junctions that are crucial in maintaining the concentration differences of small hydrophilic molecules across epithelial cell sheets. They do so in two ways. First, they seal the plasma membranes of adjacent cells together to create a continuous impermeable, or semipermeable, barrier to diffusion across the cell sheet. Second, they act as barriers in the lipid bilayer to restrict the diffusion of membrane transport proteins between the apical and the basolateral domains of the plasma membrane in each epithelial cell. Septate junctions serve as occluding junctions in invertebrate tissues.

The main types of anchoring junctions in vertebrate tissues are adherens junctions, desmosomes, focal adhesions, and hemidesmosomes. Adherens junctions and desmosomes connect cells together and are formed by cadherins, while focal adhesions and hemidesmosomes connect cells to the extracellular matrix and are formed by integrins. Adherens junctions and focal adhesions are connecting sites for bundles of actin filaments, whereas desmosomes and hemidesmosomes are connecting sites for intermediate filaments.

Gap junctions are communicating junctions composed of clusters of connexons that allow molecules smaller than about 1000 daltons to pass directly from the inside of one cell to the inside of the next. Cells connected by gap junctions share many of their inorganic ions and other small molecules and are therefore chemically and electrically coupled. Gap junctions are important in coordinating the activities of electrically active cells, and they have a coordinating role in other groups of cells as well. Plasmodesmata are the only intercellular junctions in plants. Although their structure is entirely different, and they can sometimes transport informational macromolecules, in general, they function like gap junctions. [↑ TOP](#)

Figure 19-2. The role of tight junctions in transcellular transport. Transport proteins are confined to different regions of the plasma membrane in epithelial cells of the small intestine. This segregation permits a vectorial transfer of nutrients across the epithelium from the gut lumen to the blood. In the example shown, glucose is actively transported into the cell by Na^+ -driven glucose symports at the apical surface, and it diffuses out of the cell by facilitated diffusion mediated by glucose carriers in the basolateral membrane. Tight junctions are thought to confine the transport proteins to their appropriate membrane domains by acting as diffusion barriers within the lipid bilayer of the

plasma membrane; these junctions also block the backflow of glucose from the basal side of the epithelium into the gut lumen.

Figure 19-4. The structure of a tight junction between epithelial cells of the small intestine. The junctions are shown (A) schematically, (B) in a freeze-fracture electron micrograph, and (C) in a conventional electron micrograph. Note that the cells are oriented with their apical ends down. In (B), the plane of the micrograph is parallel to the plane of the membrane, and the tight junction appears as a beltlike band of branching sealing strands that encircle each cell in the epithelium. The sealing strands are seen as ridges of intramembrane particles on the cytoplasmic fracture face of the membrane (the P face) or as complementary grooves on the external face of the membrane (the E face) (see [Figure 19-5A](#)). In (C), the junction is seen in cross section as a series of focal connections between the outer leaflets of the two interacting plasma membranes, each connection corresponding to a sealing strand in cross section. Figure 19-9. Adherens junctions. (A) Adherens junctions, in the form of adhesion belts, between epithelial cells in the small intestine. The beltlike junction encircles each of the interacting cells. Its most obvious feature is a contractile bundle of actin filaments running along the cytoplasmic surface of the junctional plasma membrane. (B) Some of the molecules that form an adherens junction. The actin filaments are joined from cell to cell by transmembrane adhesion proteins called cadherins. The cadherins form homodimers in the plasma membrane of each interacting cell. The extracellular domain of one cadherin dimer binds to the extracellular domain of an identical cadherin dimer on the adjacent cell. The intracellular tails of the cadherins bind to anchor proteins that tie them to actin filaments. These anchor proteins include α -catenin, β -catenin, γ -catenin (also called plakoglobin), α -actinin, and vinculin.

Figure 19-17. Gap junction coupling in the ovarian follicle. The oocyte is surrounded by a thick layer of extracellular matrix called the zona pellucida (discussed in [Chapter 20](#)). The surrounding granulosa cells are coupled to each other by gap junctions formed by connexin 43 (Cx43). In addition, the granulosa cells extend processes through the zona pellucida and make gap junctions with the oocyte. These gap junctions contain a different connexin (Cx37). Mutations in the gene encoding Cx37 cause infertility by disrupting the development of both the granulosa cells and the oocyte.

Molecular Biology of the Cell ➔ V. Cells in Their Social Context ➔ 19. Cell Junctions, Cell Adhesion, and the Extracellular Matrix

Cell-Cell Adhesion

To form an anchoring junction, cells must first adhere. A bulky cytoskeletal apparatus must then be assembled around the molecules that directly mediate the adhesion. The result is a well-defined structure—a desmosome, a hemidesmosome, a focal adhesion, or an adherens junction—that is easily identified in the electron microscope. Indeed, electron microscopy provided the basis for the original classification of cell junctions. In the early stages of cell junction development, however, before the cytoskeletal apparatus has assembled, cells often adhere to one another without clearly displaying these characteristic structures; in the electron microscope, one may simply see two plasma membranes separated by a small gap of a definite width. Functional tests show, nevertheless, that the two cells are stuck to each other, and biochemical analysis can reveal the molecules responsible for the adhesion.

The study of cell-cell junctions and the study of cell-cell adhesion were once quite distinct endeavors, originating from two different experimental approaches—junctions through electron microscopic description, and adhesion through functional tests and biochemistry. Only in recent years have these two approaches begun to converge in a unified view of the molecular basis of cell junctions and cell adhesion. In the previous section, we concentrated on the structures of mature cell junctions. In this section, we turn to functional and biochemical studies of the cell-cell adhesion mechanisms that operate when cells migrate over other cells and when they assemble into tissues—mechanisms that precede the construction of mature cell-cell anchoring junctions. We begin with a critical question for embryonic development: what mechanisms ensure that a cell attaches to appropriate neighbors at the right time?

Animal Cells Can Assemble into Tissues Either in Place or After They Migrate

Many simple tissues, including most epithelial tissues, derive from precursor cells whose progeny are prevented from wandering away by being attached to the extracellular matrix, to other cells, or to both (Figure 19-22). But the accumulating cells do not simply remain passively stuck together; instead, the

tissue architecture is generated and actively maintained by selective adhesions that the cells make and progressively adjust.

Selective adhesion is even more essential for the development of tissues that have more complex origins involving cell migration. In these tissues, one population of cells invades another and assembles with it, and perhaps with other migrant cells, to form an orderly structure. In vertebrate embryos, for example, cells from the *neural crest* break away from the epithelial neural tube, of which they are initially a part, and migrate along specific paths to many other regions (discussed in [Chapter 21](#)). There they assemble with other cells and with one another to differentiate into a variety of tissues, including those of the peripheral nervous system ([Figure 19-23](#)).

Cell motility and cell adhesion combine to bring about these kinds of morphogenetic events. The process requires some mechanism for directing the cells to their final destination. This may involve *chemotaxis* or *chemorepulsion*, the secretion of a soluble chemical that attracts or repels migrating cells, respectively, or *pathway guidance*, the laying down of adhesive or repellent molecules in the extracellular matrix or on cell surfaces to guide the migrating cells along the right paths. Then, once a migrating cell has reached its destination, it must recognize and join other cells of the appropriate type to assemble into a tissue. How this latter process occurs can be studied if cells of different embryonic tissues are artificially mingled, after which they often spontaneously sort out to restore a more normal arrangement, as we discuss next. [↑ TOP](#)

Dissociated Vertebrate Cells Can Reassemble into Organized Tissues Through Selective Cell-Cell Adhesion

Unlike adult vertebrate tissues, which are difficult to dissociate, embryonic vertebrate tissues are easily dissociated. This is usually done by treating the tissue with low concentrations of a proteolytic enzyme such as trypsin, sometimes combined with the removal of extracellular Ca^{2+} and Mg^{2+} with a divalent-cation chelator (such as EDTA). These reagents disrupt the protein-protein interactions (many of which are divalent-cation-dependent) that hold cells together. Remarkably, the dissociated cells often reassemble *in vitro* into structures that resemble the original tissue. Such findings reveal that tissue structure is not just a product of history; it is actively maintained and stabilized by the system of affinities that cells have for one another and for the extracellular matrix.

A striking example of this phenomenon is seen when dissociated cells from two embryonic vertebrate organs, such as the liver and the retina, are mixed together and artificially formed into a pellet: the mixed aggregates gradually sort out according to their organ of origin. More generally, disaggregated cells are found to adhere more readily to aggregates of their own organ than to aggregates of other organs. Evidently there are cell-cell recognition systems

that make cells of the same differentiated tissue preferentially adhere to one another; these adhesive preferences are presumably important in stabilizing tissue architecture.

Cells adhere to each other and to the extracellular matrix through cell-surface proteins called **cell adhesion molecules (CAMs)**—a category that includes the transmembrane adhesion proteins we have already discussed. CAMs can be *cell-cell adhesion molecules* or *cell-matrix adhesion molecules*. Some CAMs are Ca^{2+} -dependent, whereas others are Ca^{2+} -independent. The Ca^{2+} -dependent CAMs seem to be primarily responsible for the tissue-specific cell-cell adhesion seen in early vertebrate embryos, explaining why these cells can be disaggregated with Ca^{2+} -chelating agents.

CAMs were initially identified by making antibodies against cell-surface molecules and then testing the antibodies for their ability to inhibit cell-cell adhesion in a test tube. Those rare antibodies that inhibit the adhesion were then used to characterize and isolate the adhesion molecule recognized by the antibodies. [↑ TOP](#)

Cadherins Mediate Ca^{2+} -dependent Cell-Cell Adhesion

The cadherins are the major CAMs responsible for Ca^{2+} -dependent cell-cell adhesion in vertebrate tissues. The first three cadherins that were discovered were named according to the main tissues in which they were found: *E-cadherin* is present on many types of epithelial cells; *N-cadherin* on nerve, muscle, and lens cells; and *P-cadherin* on cells in the placenta and epidermis. All are also found in various other tissues; N-cadherin, for example, is expressed in fibroblasts, and E-cadherin is expressed in parts of the brain. These and other **classical cadherins** are related in sequence throughout their extracellular and intracellular domains. There are also a large number of **nonclassical cadherins**, with more than 50 expressed in the brain alone. The nonclassical cadherins include proteins with known adhesive function, such as the desmosomal cadherins discussed earlier and the diverse *protocadherins* found in the brain. They also include proteins that appear to have nonadhesive functions, such as *T-cadherin*, which lacks a transmembrane domain and is attached to the plasma membrane of nerve and muscle cells by a glycosylphosphatidylinositol (GPI) anchor, and the *Fat protein*, which was first identified as the product of a tumor-suppressor gene in *Drosophila*. Together, the classical and nonclassical cadherin proteins constitute the **cadherin superfamily** ([Table 19-3](#)).

Cadherins are expressed in both invertebrates and vertebrates. Virtually all vertebrate cells seem to express one or more cadherins, according to the cell type. They are the main adhesion molecules holding cells together in early embryonic tissues. In culture, the removal of extracellular Ca^{2+} or treatment with anti-cadherin antibodies disrupts embryonic tissues, and, if cadherin-mediated adhesion is left intact, antibodies against other adhesion molecules

have little effect. Mutations that inactivate the function of E-cadherin cause mouse embryos to fall apart and die early in development.

Most cadherins are single-pass transmembrane glycoproteins about 700–750 amino acids long. Structural studies suggest that they associate in the plasma membrane to form dimers or larger oligomers. The large extracellular part of the polypeptide chain is usually folded into five or six *cadherin repeats*, which are structurally related to immunoglobulin (Ig) domains ([Figure 19-24A and B](#)). The crystal structures of E- and N-cadherin have helped to explain the importance of Ca^{2+} binding for cadherin function. The Ca^{2+} ions are positioned between each pair of cadherin repeats, locking the repeats together to form a stiff, rodlike structure: the more Ca^{2+} ions that are bound, the more rigid the structure is. If Ca^{2+} is removed, the extracellular part of the protein becomes floppy and is rapidly degraded by proteolytic enzymes ([Figure 19-24C](#)). [↑ TOP](#)

Cadherins Have Crucial Roles in Development

E-cadherin is the best-characterized cadherin. It is usually concentrated in adherens junctions in mature epithelial cells, where it helps connect the cortical actin cytoskeletons of the cells it holds together (see [Figure 19-9B](#)). E-cadherin is also the first cadherin expressed during mammalian development. It helps cause compaction, an important morphological change that occurs at the eight-cell stage of mouse embryo development. During compaction, the loosely attached cells, called *blastomeres*, become tightly packed together and joined by intercellular junctions. Antibodies against E-cadherin block blastomere compaction, whereas antibodies that react with various other cell-surface molecules on these cells do not.

It seems likely that cadherins are also crucial in later stages of vertebrate development, since their appearance and disappearance correlate with major morphogenetic events in which tissues segregate from one another. As the neural tube forms and pinches off from the overlying ectoderm, for example, neural tube cells lose E-cadherin and acquire other cadherins, including N-cadherin, while the cells in the overlying ectoderm continue to express E-cadherin ([Figure 19-25](#)). Then, when the neural crest cells migrate away from the neural tube, these cadherins become scarcely detectable, and another cadherin (cadherin-7) appears that helps hold the migrating cells together as loosely associated cell groups. Finally, when the cells aggregate to form a ganglion, they re-express N-cadherin (see [Figure 19-23](#)).

If N-cadherin is overexpressed in the emerging neural crest cells, the cells fail to escape from the neural tube. Thus, not only do cell groups that originate from one cell layer exhibit distinct patterns of cadherin expression when separating from one another, but these switches in cadherin expression seem to be intimately involved in the separation process. [↑ TOP](#)

Cadherins Mediate Cell-Cell Adhesion by a Homophilic Mechanism

How do cell-cell adhesion molecules such as the cadherins bind cells together? Three possibilities are illustrated in [Figure 19-26](#): (1) in *homophilic binding*, molecules on one cell bind to other molecules of the same kind on adjacent cells; (2) in *heterophilic binding*, the molecules on one cell bind to molecules of a different kind on adjacent cells; (3) in *linker-dependent binding*, cell-surface receptors on adjacent cells are linked to one another by secreted multivalent linker molecules. Although all three mechanisms have been found to operate in animals, cadherins usually link cells by the homophilic mechanism. In a line of cultured fibroblasts called *L cells*, for example, the cells neither express cadherins nor adhere to one another. When *L cells* are transfected with DNA encoding E-cadherin, the transfected cells become adherent to one another by a Ca^{2+} -dependent mechanism, and the adhesion is inhibited by anti-E-cadherin antibodies. Since cadherin proteins can bind directly to one another and the transfected cells do not bind to untransfected *L cells*, one can conclude that E-cadherin binds cells together through the interaction of two E-cadherin molecules on different cells.

If *L cells* expressing different cadherins are mixed together, they sort out and aggregate separately, indicating that different cadherins preferentially bind to their own type ([Figure 19-27A](#)), mimicking what happens when cells derived from tissues that express different cadherins are mixed together. A similar segregation of cells occurs if *L cells* expressing different amounts of the same cadherin are mixed together ([Figure 19-27B](#)). It therefore seems likely that both qualitative and quantitative differences in the expression of cadherins have a role in organizing tissues.

In the nervous system especially, there are many different cadherins, each with a distinct but overlapping pattern of expression ([Figure 19-28A](#)). As they are concentrated at synapses, they are thought to have a role in synapse formation and stabilization. Some of the nonclassical cadherins, such as the protocadherins, are strong candidates for helping to determine the specificity of synaptic connections. Like antibodies, they differ in their N-terminal (variable) regions but are identical in their C-terminal (constant) regions. The extracellular variable region and intracellular constant region are encoded by separate exons, with the variable-region exons arranged in tandem arrays upstream of the constant-region exons ([Figure 19-28B](#)). The diversity of protocadherins is generated by a combination of differential promoter usage and alternative RNA splicing, rather than by site-specific recombination as occurs in antibody diversification (discussed in [Chapter 24](#)). [↑ TOP](#)

Cadherins Are Linked to the Actin Cytoskeleton by Catenins

Most cadherins, including all classical and some nonclassical ones, function as

transmembrane adhesion proteins that indirectly link the actin cytoskeletons of the cells they join together. This arrangement occurs in adherens junctions (see [Figure 19-9B](#)). The highly conserved cytoplasmic tail of these cadherins interacts indirectly with actin filaments by means of a group of intracellular anchor proteins called **catenins** ([Figure 19-29](#)). This interaction is essential for efficient cell-cell adhesion, as classical cadherins that lack their cytoplasmic domain cannot hold cells strongly together.

As discussed earlier, the nonclassical cadherins that form desmosomes interact with intermediate filaments, rather than with actin filaments. Their cytoplasmic domain binds to a different set of intracellular anchor proteins, which in turn bind to intermediate filaments (see [Figure 19-11D](#)).

Some cells can regulate the adhesive activity of their cadherins. This regulation may be important for the cellular rearrangements that occur within epithelia when these cell sheets change their shape and organization during animal development (see [Figure 19-10](#)). The molecular basis of this regulation is uncertain but may involve the phosphorylation of anchor proteins attached to the cytoplasmic tail of the cadherins.

Some cadherins can help transmit signals to the cell interior. Vascular endothelial cadherin (VE-cadherin), for example, not only mediates adhesion between endothelial cells but also is required for endothelial cell survival. Although endothelial cells that do not express VE-cadherin still adhere to one another via N-cadherin, they do not survive (see [Table 19-3](#), p. 1082). Their survival depends on an extracellular signal protein called *vascular endothelial growth factor (VEGF)*, which binds to a receptor tyrosine kinase (discussed in [Chapter 15](#)) that uses VE-cadherin as a co-receptor. [↑ TOP](#)

Selectins Mediate Transient Cell-Cell Adhesions in the Bloodstream

White blood cells lead a nomadic life, moving to and fro between the bloodstream and the tissues, and this necessitates special adhesive properties. These properties depend on selectins. Selectins are cell-surface carbohydrate-binding proteins (*lectins*) that mediate a variety of transient, Ca^{2+} -dependent, cell-cell adhesion interactions in the bloodstream. There are at least three types: *L-selectin* on white blood cells, *P-selectin* on blood platelets and on endothelial cells that have been locally activated by an inflammatory response, and *E-selectin* on activated endothelial cells. Each selectin is a transmembrane protein with a highly conserved lectin domain that binds to a specific oligosaccharide on another cell ([Figure 19-30A](#)).

Selectins have an important role in binding white blood cells to endothelial cells lining blood vessels, thereby enabling the blood cells to migrate out of the bloodstream into a tissue. In a lymphoid organ, the endothelial cells express

oligosaccharides that are recognized by L-selectin on lymphocytes, causing the lymphocytes to loiter and become trapped. Conversely, at sites of inflammation, the endothelial cells switch on expression of selectins, which recognize the oligosaccharides on white blood cells and platelets, flagging the cells down to help deal with the local emergency. Selectins do not act alone, however; they collaborate with integrins, which strengthen the binding of the blood cells to the endothelium. The cell-cell adhesions mediated by both selectins and integrins are heterophilic (see [Figure 19-26](#)): selectins bind to specific oligosaccharides on glycoproteins and glycolipids, while integrins bind to specific proteins.

Selectins and integrins act in sequence to let white blood cells leave the bloodstream and enter tissues. The selectins mediate a weak adhesion because the binding of the lectin domain of the selectin to its carbohydrate ligand is of low affinity. This allows the white blood cell to adhere weakly and reversibly to the endothelium, rolling along the surface of the blood vessel propelled by the flow of blood. The rolling continues until the blood cell activates its integrins (discussed later), now causing the cell to bind strongly to the endothelial cell surface and to crawl out of the blood vessel between adjacent endothelial cells ([Figure 19-30B](#)). [↑ TOP](#)

Members of the Immunoglobulin Superfamily of Proteins Mediate Ca^{2+} -independent Cell-Cell Adhesion

Cadherins, selectins, and integrins all depend on extracellular Ca^{2+} (or Mg^{2+} for some integrins) to function in cell adhesion. The molecules responsible for Ca^{2+} -independent cell-cell adhesion belong mainly to the large and ancient *immunoglobulin (Ig) superfamily* of proteins. These proteins contain one or more Ig-like domains that are characteristic of antibody molecules (discussed in [Chapter 24](#)). One of the best-studied examples is the **neural cell adhesion molecule (N-CAM)**, which is expressed by a variety of cell types, including most nerve cells. N-CAM is the most prevalent of the Ca^{2+} -independent cell-cell adhesion molecules in vertebrates, and, like cadherins, it is thought to bind cells together by a homophilic mechanism (between N-CAM molecules on adjacent cells). Some Ig-like cell-cell adhesion proteins, however, use a heterophilic mechanism. *Intercellular adhesion molecules (ICAMs)* on endothelial cells, for example, bind to integrins on blood cells when blood cells migrate out of the bloodstream, as just discussed.

There are at least 20 forms of N-CAM, all generated by alternative splicing of an RNA transcript produced from a single gene. In all forms, the large extracellular part of the polypeptide chain is folded into five Ig-like domains ([Figure 19-31](#)). Some forms of N-CAM carry an unusually large quantity of sialic acid (with chains containing hundreds of repeating sialic acid units). By virtue of their negative charge, these long polysialic acid chains hinder cell adhesion, and there is increasing evidence that N-CAM heavily loaded with sialic acid serves to prevent adhesion, rather than cause it.

Although cadherins and Ig family members are frequently expressed on the same cells, the adhesions mediated by cadherins are much stronger, and they are largely responsible for holding cells together, segregating cell collectives into discrete tissues, and maintaining tissue integrity. N-CAM and other members of the Ig family seem to contribute more to the fine-tuning of these adhesive interactions during development and regeneration. In the developing rodent pancreas, for example, the formation of the islets of Langerhans requires cell aggregation, followed by cell sorting. Whereas inhibition of cadherin function prevents cell aggregation and islet formation, loss of N-CAM only impairs the cell sorting process, so that disorganized islets form.

Similarly, whereas mutant mice that lack N-cadherin die early in development, mutant mice that lack N-CAM develop relatively normally, although they do have some defects in neural development. Mutations in other genes that encode Ig-like cell adhesion proteins, however, can cause more severe neural defects. *L1* gene mutations in humans, for example, cause mental retardation and other neurological defects resulting from abnormalities in the migration of nerve cells and their axons.

The importance of Ig-like cell adhesion proteins in connecting the neurons of the developing nervous system has been demonstrated dramatically in *Drosophila*. An N-CAM-like protein called *fasciclin III (FAS3)* is expressed transiently on some motor neurons, as well as on the muscle cells they normally innervate. If FAS3 is genetically removed from these neurons, they fail to recognize their muscle targets and do not make synapses with them. Conversely, if motor neurons that normally do not express FAS3 are made to express this protein, they now synapse with FAS3-expressing muscle cells to which they normally do not connect. It seems that FAS3 mediates these synaptic connections by a homophilic "matchmaking" mechanism.

Like the cadherins, some Ig-like proteins do more than just bind cells together. They can also transmit signals to the cell interior. Some forms of N-CAM in nerve cells, for example, associate with *Src family* cytoplasmic tyrosine kinases (discussed in [Chapter 15](#)), which relay signals onward by phosphorylating intracellular proteins on tyrosines. Other Ig family members are transmembrane tyrosine phosphatases (discussed in [Chapter 15](#)) that help guide growing axons to their target cells, presumably by dephosphorylating specific intracellular proteins. [↑ TOP](#)

Multiple Types of Cell-Surface Molecules Act in Parallel to Mediate Selective Cell-Cell Adhesion

A single type of cell utilizes multiple molecular mechanisms in adhering to other cells. Some of these mechanisms involve organized cell junctions, while others do not ([Figure 19-32](#)). Each cell in a multicellular animal contains an assortment of cell-surface receptors that enables the cell to respond specifically

to a complementary set of soluble extracellular signal molecules, such as hormones and growth factors. Likewise, each cell in a tissue has a particular combination (and concentration) of cell-surface adhesion molecules that enables it to bind in its own characteristic way to other cells and to the extracellular matrix. And just as receptors for soluble extracellular signal molecules generate intracellular signals that alter the cell's behavior, so too can cell adhesion molecules, although the signaling mechanisms they use are generally not as well understood.

Unlike receptors for soluble signal molecules, which bind their specific ligand with high affinity, the receptors that bind to molecules on cell surfaces or in the extracellular matrix usually do so with relatively low affinity. These low-affinity receptors rely on the enormous increase in binding strength gained through the simultaneous binding of multiple receptors to multiple ligands on an opposing cell or in the adjacent matrix. One could call this the "Velcro principle."

We have seen, however, that the interaction of the extracellular binding domains of these cell-surface molecules is not enough to ensure cell adhesion. At least in the case of cadherins and, as we shall see, integrins, the adhesion molecules must also attach (via anchor proteins) to the cytoskeleton inside the cell. The cytoskeleton is thought to assist and stabilize the lateral clustering of the adhesion molecules to facilitate multipoint binding. The cytoskeleton is also required to enable the adhering cell to exert traction on the adjacent cell or matrix (and vice versa). Thus, the mixture of specific types of cell-cell adhesion molecules present on any two cells, as well as their concentration, cytoskeletal linkages, and distribution on the cell surface, determine the total affinity with which the two cells bind to each other. [↑ TOP](#)

Nonjunctional Contacts May Initiate Cell-Cell Adhesions That Junctional Contacts Then Orient and Stabilize

We have seen that adhesive contacts between cells play a crucial part in organizing the formation of tissues and organs in developing embryos or in adult tissues undergoing repair after injury. Most often, these contacts do not involve the formation of organized intercellular junctions that show up as specialized structures in the electron microscope. The interacting plasma membranes are simply seen to come close together and run parallel, separated by a space of 10–20 nm. This type of "nonjunctional" contact may be optimal for cell locomotion—close enough to provide traction and to allow transmembrane adhesion proteins to interact, but not so tight, or so solidly anchored to the cytoskeleton, as to immobilize the cell.

A reasonable hypothesis is that nonjunctional cell-cell adhesion proteins initiate cell-cell adhesions, which are then oriented and stabilized by the assembly of full-blown intercellular junctions. Many of the transmembrane proteins involved can diffuse in the plane of the plasma membrane and, in this

or other ways, can be recruited to sites of cell-cell (and cell-matrix) contact, enabling nonjunctional adhesions to enlarge and mature into junctional adhesions. This has been demonstrated for some integrins and cadherins, which help initiate cell adhesion and then later become integral parts of cell junctions. The migrating tip of an axon, for example, has an even distribution of cadherins on its surface, which helps it adhere to other cells along the migration pathway. It also has an intracellular pool of cadherins in vesicles just under the plasma membrane. When the axon reaches its target cell, it is thought to release the intracellular cadherin molecules onto the cell surface, where they help form a stable contact, which matures into a chemical synapse.

As discussed earlier, antibodies against adherens junction proteins block the formation of tight junctions, as well as adherens junctions, suggesting that the assembly of one type of junction can be a prerequisite for the formation of another. An increasing number of monoclonal antibodies and peptide fragments have been produced that can block a single type of cell adhesion molecule. Moreover, an increasing number of genes encoding these cell-surface proteins have been identified, creating new opportunities for manipulating the adhesive machinery of cells in culture and in experimental animals. It is now possible, therefore, to inactivate the various cell-cell adhesion proteins in combinations—a requirement for deciphering the rules of cell-cell recognition and binding used to build complex tissues. [↑ TOP](#)

Summary

Cells dissociated from various tissues of vertebrate embryos preferentially reassociate with cells from the same tissue when they are mixed together. This tissue-specific recognition process in vertebrates is mediated mainly by a family of Ca^{2+} -dependent cell-cell adhesion proteins called cadherins, which hold cells together by a homophilic interaction between these transmembrane proteins on adjacent cells. For this interaction to be effective, the cytoplasmic part of the cadherins must be linked to the cytoskeleton by cytoplasmic anchor proteins called catenins.

Two other families of transmembrane adhesion proteins have major roles in cell-cell adhesion. Selectins function in transient Ca^{2+} -dependent cell-cell adhesions in the bloodstream by binding to specific oligosaccharides on the surface of another cell. Members of the immunoglobulin superfamily, including N-CAM, mediate Ca^{2+} -independent cell-cell adhesion processes that are especially important during neural development.

Even a single cell type uses multiple molecular mechanisms in adhering to other cells (and to the extracellular matrix). Thus, the specificity of cell-cell (and cell-matrix) adhesion seen in embryonic development must result from the integration of several different adhesion systems, of which some are associated with specialized cell junctions, while others are not. Figure 19-23. An example of a more complex mechanism by which cells

assemble to form a tissue. Some cells that are initially part of the epithelial neural tube alter their adhesive properties and disengage from the epithelium to form the neural crest on the upper surface of the neural tube. The cells then migrate away and form a variety of cell types and tissues throughout the embryo. Here they are shown assembling and differentiating to form two collections of nerve cells, called ganglia, in the peripheral nervous system. Other neural crest cells differentiate in the ganglion to become supporting (satellite) cells surrounding the neurons. The crest cells tend to migrate in clusters, and they proliferate rapidly as they migrate.

Figure 19-24. The structure and function of cadherins. (A) A classical cadherin molecule. The protein is a homodimer, with the extracellular part of each polypeptide folded into five cadherin repeats. There are Ca^{2+} -binding sites between each pair of repeats. (B) The crystal structure of a single cadherin repeat, which resembles an immunoglobulin (Ig) domain. (C) The influence of extracellular Ca^{2+} . As the amount of Ca^{2+} increases, the extracellular parts of the cadherin chains become more rigid. When enough Ca^{2+} is bound, the cadherin dimer extends from the surface, where it can bind to a cadherin dimer on a neighboring cell. If Ca^{2+} is removed, the extracellular part of the protein becomes floppy and is degraded by proteolytic enzymes.

Figure 19-32. A summary of the junctional and nonjunctional adhesive mechanisms used by animal cells in binding to one another and to the extracellular matrix. The junctional mechanisms are shown in epithelial cells, while the nonjunctional mechanisms are shown in nonepithelial cells. A junctional adhesion is operationally defined as one that can be seen as a specialized region of contact by conventional or freeze-fracture electron microscopy. A nonjunctional adhesion shows no such obvious specialized structure. Note that the integrins and cadherins are involved in both nonjunctional and junctional cell-cell (cadherins) and cell-matrix (integrins) contacts. Cadherins generally mediate homophilic interactions, whereas integrins mediate heterophilic interactions (see [Figure 19-26](#)). The

cadherins, integrins, and selectins act as transmembrane adhesion molecules and depend on extracellular divalent cations to function; for this reason, most cell-cell and cell-matrix contacts are divalent-cation-dependent. On blood cells, selectins and integrins can also act as heterophilic cell-cell adhesion molecules: the selectins bind to carbohydrate, while the cell-binding integrins bind to members of the Ig superfamily. The integrins and integral membrane proteoglycans that mediate nonjunctional adhesion to the extracellular matrix are discussed later. (Insert courtesy of Daniel S. Friend.)

Molecular Biology of the Cell ➔ V. Cells in Their Social Context ➔ 19. Cell Junctions, Cell Adhesion, and the Extracellular Matrix

The Extracellular Matrix of Animals

Tissues are not made up solely of cells. A substantial part of their volume is *extracellular space*, which is largely filled by an intricate network of macromolecules constituting the extracellular matrix (Figure 19-33). This matrix is composed of a variety of proteins and polysaccharides that are secreted locally and assembled into an organized meshwork in close association with the surface of the cell that produced them.

Whereas we have discussed cell junctions chiefly in the context of epithelial tissues, our account of the extracellular matrix concentrates on connective tissues (Figure 19-34). The extracellular matrix in connective tissue is frequently more plentiful than the cells it surrounds, and it determines the tissue's physical properties. Connective tissues form the framework of the vertebrate body, but the amounts found in different organs vary greatly—from cartilage and bone, in which they are the major component, to brain and spinal cord, in which they are only minor constituents.

Variations in the relative amounts of the different types of matrix macromolecules and the way in which they are organized in the extracellular matrix give rise to an amazing diversity of forms, each adapted to the functional requirements of the particular tissue. The matrix can become calcified to form the rock-hard structures of bone or teeth, or it can form the transparent matrix of the cornea, or it can adopt the ropelike organization that gives tendons their enormous tensile strength. At the interface between an epithelium and connective tissue, the matrix forms a basal lamina (see Figure 19-34), which is important in controlling cell behavior.

The vertebrate extracellular matrix was once thought to serve mainly as a relatively inert scaffold to stabilize the physical structure of tissues. But now it is clear that the matrix has a far more active and complex role in regulating the behavior of the cells that contact it, influencing their survival, development, migration, proliferation, shape, and function. The extracellular matrix has a correspondingly complex molecular composition. Although our understanding of its organization is still incomplete, there has been rapid progress in characterizing many of its major components.

We focus on the extracellular matrix of vertebrates, but the origins of the extracellular matrix are very ancient and virtually all multicellular organisms, make it; examples include the cuticles of worms and insects, the shells of mollusks, and, as we discuss later, the cell walls of plants.

The Extracellular Matrix Is Made and Oriented by the Cells Within It

The macromolecules that constitute the extracellular matrix are mainly produced locally by cells in the matrix. As we discuss later, these cells also help to organize the matrix: the orientation of the cytoskeleton inside the cell can control the orientation of the matrix produced outside. In most connective tissues, the matrix macromolecules are secreted largely by cells called **fibroblasts** (Figure 19-35). In certain specialized types of connective tissues, such as cartilage and bone, however, they are secreted by cells of the fibroblast family that have more specific names: *chondroblasts*, for example, form cartilage, and *osteoblasts* form bone.

Two main classes of extracellular macromolecules make up the matrix: (1) polysaccharide chains of the class called *glycosaminoglycans* (GAGs), which are usually found covalently linked to protein in the form of *proteoglycans*, and (2) fibrous proteins, including *collagen*, *elastin*, *fibronectin*, and *laminin*, which have both structural and adhesive functions. We shall see that the members of both classes come in a great variety of shapes and sizes.

The proteoglycan molecules in connective tissue form a highly hydrated, gel-like "ground substance" in which the fibrous proteins are embedded. The polysaccharide gel resists compressive forces on the matrix while permitting the rapid diffusion of nutrients, metabolites, and hormones between the blood and the tissue cells. The collagen fibers both strengthen and help organize the matrix, and rubberlike elastin fibers give it resilience. Finally, many matrix proteins help cells attach in the appropriate locations. [↑ TOP](#)

Glycosaminoglycan (GAG) Chains Occupy Large Amounts of Space and Form Hydrated Gels

Glycosaminoglycans (GAGs) are unbranched polysaccharide chains composed of repeating disaccharide units. They are called GAGs because one of the two sugars in the repeating disaccharide is always an amino sugar (*N*-acetylglucosamine or *N*-acetylgalactosamine), which in most cases is sulfated. The second sugar is usually a uronic acid (glucuronic or iduronic). Because there are sulfate or carboxyl groups on most of their sugars, GAGs are highly negatively charged (Figure 19-36). Indeed, they are the most anionic molecules produced by animal cells. Four main groups of GAGs are distinguished according to their sugars, the type of linkage between the sugars, and the number and location of sulfate groups: (1) *hyaluronan*, (2) *chondroitin*

Tables

sulfate and dermatan sulfate, (3) heparan sulfate, and (4) keratan sulfate.

Polysaccharide chains are too stiff to fold up into the compact globular structures that polypeptide chains typically form. Moreover, they are strongly hydrophilic. Thus, GAGs tend to adopt highly extended conformations that occupy a huge volume relative to their mass ([Figure 19-37](#)), and they form gels even at very low concentrations. Their high density of negative charges attracts a cloud of cations, most notably Na^+ , that are osmotically active, causing large amounts of water to be sucked into the matrix. This creates a swelling pressure, or turgor, that enables the matrix to withstand compressive forces (in contrast to collagen fibrils, which resist stretching forces). The cartilage matrix that lines the knee joint, for example, can support pressures of hundreds of atmospheres in this way.

The GAGs in connective tissue usually constitute less than 10% of the weight of the fibrous proteins. But, because they form porous hydrated gels, the GAG chains fill most of the extracellular space, providing mechanical support to the tissue. In one rare human genetic disease, there is a severe deficiency in the synthesis of the dermatan sulfate disaccharide shown in [Figure 19-36](#). The affected individuals have a short stature, prematurely aged appearance, and generalized defects in their skin, joints, muscles, and bones.

It should be emphasized, however, that, in invertebrates and plants, other types of polysaccharides often dominate the extracellular matrix. Thus, in higher plants, as we discuss later, cellulose (polyglucose) chains are packed tightly together in ribbonlike crystalline arrays to form the microfibrillar component of the cell wall. In insects, crustaceans, and other arthropods, chitin (poly-*N*-acetylglucosamine) similarly forms the main component of the exoskeleton. Together, cellulose and chitin are the most abundant biopolymers on Earth. [↑ TOP](#)

Hyaluronan Is Thought to Facilitate Cell Migration During Tissue Morphogenesis and Repair

Hyaluronan (also called *hyaluronic acid* or *hyaluronate*) is the simplest of the GAGs ([Figure 19-38](#)). It consists of a regular repeating sequence of up to 25,000 nonsulfated disaccharide units, is found in variable amounts in all tissues and fluids in adult animals, and is especially abundant in early embryos. Hyaluronan is not typical of the majority of GAGs. In contrast with all of the others, it contains no sulfated sugars, all its disaccharide units are identical, its chain length is enormous (thousands of sugar monomers), and it is not generally linked covalently to any core protein. Moreover, whereas other GAGs are synthesized inside the cell and released by exocytosis, hyaluronan is spun out directly from the cell surface by an enzyme complex embedded in the plasma membrane.

Hyaluronan is thought to have a role in resisting compressive forces in tissues

and joints. It is also important as a space filler during embryonic development, where it can be used to force a change in the shape of a structure, as a small quantity expands with water to occupy a large volume (see [Figure 19-37](#)).

Hyaluronan synthesized from the basal side of an epithelium, for example, often serves to create a cell-free space into which cells subsequently migrate; this occurs in the formation of the heart, the cornea, and several other organs. When cell migration ends, the excess hyaluronan is generally degraded by the enzyme *hyaluronidase*. Hyaluronan is also produced in large quantities during wound healing, and it is an important constituent of joint fluid, where it serves as a lubricant.

Many of the functions of hyaluronan depend on specific interactions with other molecules, including both proteins and proteoglycans—molecules consisting of GAG chains covalently linked to a protein. Some of these molecules that bind to hyaluronan are constituents of the extracellular matrix, while others are integral components of the surface of cells. [↑ TOP](#)

Proteoglycans Are Composed of GAG Chains Covalently Linked to a Core Protein

Except for hyaluronan, all GAGs are found covalently attached to protein in the form of proteoglycans, which are made by most animal cells. The polypeptide chain, or *core protein*, of a proteoglycan is made on membrane-bound ribosomes and threaded into the lumen of the endoplasmic reticulum. The polysaccharide chains are mainly assembled on this core protein in the Golgi apparatus. First, a special *link tetrasaccharide* is attached to a serine side chain on the core protein to serve as a primer for polysaccharide growth; then, one sugar at a time is added by specific glycosyl transferases ([Figure 19-39](#)). While still in the Golgi apparatus, many of the polymerized sugars are covalently modified by a sequential and coordinated series of reactions. Epimerizations alter the configuration of the substituents around individual carbon atoms in the sugar molecule; sulfations increase the negative charge.

Proteoglycans are usually easily distinguished from other glycoproteins by the nature, quantity, and arrangement of their sugar side chains. By definition, at least one of the sugar side chains of a proteoglycan must be a GAG. Whereas glycoproteins contain 1–60% carbohydrate by weight in the form of numerous relatively short, branched oligosaccharide chains, proteoglycans can contain as much as 95% carbohydrate by weight, mostly in the form of long, unbranched GAG chains, each typically about 80 sugars long. Proteoglycans can be huge. The proteoglycan *aggrecan*, for example, which is a major component of cartilage, has a mass of about 3×10^6 daltons with over 100 GAG chains. Other proteoglycans are much smaller and have only 1–10 GAG chains; an example is *decorin*, which is secreted by fibroblasts and has a single GAG chain ([Figure 19-40](#)).

In principle, proteoglycans have the potential for almost limitless

heterogeneity. Even a single type of core protein can vary greatly in the number and types of attached GAG chains. Moreover, the underlying repeating pattern of disaccharides in each GAG can be modified by a complex pattern of sulfate groups. The heterogeneity of these GAGs makes it difficult to identify and classify proteoglycans in terms of their sugars. The sequences of many core proteins have been determined with the aid of recombinant DNA techniques, and they, too, are extremely diverse. Although a few small families have been recognized, no common structural feature clearly distinguishes proteoglycan core proteins from other proteins, and many have one or more domains that are homologous to domains found in other proteins of the extracellular matrix or plasma membrane. Thus, it is probably best to regard proteoglycans as a diverse group of highly glycosylated glycoproteins whose functions are mediated by both their core proteins and their GAG chains. [↑ TOP](#)

Proteoglycans Can Regulate the Activities of Secreted Proteins

Given the great abundance and structural diversity of proteoglycan molecules, it would be surprising if their function were limited to providing hydrated space around and between cells. Their GAG chains, for example, can form gels of varying pore size and charge density; one possible function, therefore, is to serve as selective sieves to regulate the traffic of molecules and cells according to their size, charge, or both. Evidence suggests that a heparan sulfate proteoglycan called *perlecan* has this role in the basal lamina of the kidney glomerulus, which filters molecules passing into the urine from the bloodstream (discussed below).

Proteoglycans are thought to have a major role in chemical signaling between cells. They bind various secreted signal molecules, such as certain protein growth factors, and can enhance or inhibit their signaling activity. For example, the heparan sulfate chains of proteoglycans bind to *fibroblast growth factors* (FGFs), which stimulate a variety of cell types to proliferate; this interaction oligomerizes the growth factor molecules, enabling them to cross-link and activate their cell-surface receptors, which are transmembrane tyrosine kinases (see [Figure 15-50B](#)). Whereas in most cases the signal molecules bind to the GAG chains of the proteoglycan, this is not always so. Some members of the *transforming growth factor β* (TGF- β) family bind to the core proteins of several matrix proteoglycans, including decorin; binding to decorin inhibits the activity of the growth factors.

Proteoglycans also bind, and regulate the activities of, other types of secreted proteins, including proteolytic enzymes (proteases) and protease inhibitors. Binding to a proteoglycan could control the activity of a secreted protein in any of the following ways: (1) it could immobilize the protein close to the site where it is produced, thereby restricting its range of action; (2) it could sterically block the activity of the protein; (3) it could provide a reservoir of

the protein for delayed release; (4) it could protect the protein from proteolytic degradation, thereby prolonging its action; (5) it could alter or concentrate the protein for more effective presentation to cell-surface receptors.

Proteoglycans are thought to act in all these ways to help regulate the activities of secreted proteins. An example of the last function occurs in inflammatory responses, in which heparan sulfate proteoglycans immobilize secreted chemotactic attractants called *chemokines* (discussed in [Chapter 24](#)) on the endothelial surface of a blood vessel at an inflammatory site. In this way, the chemokines remain there for a prolonged period, stimulating white blood cells to leave the bloodstream and migrate into the inflamed tissue. [↑ TOP](#)

GAG Chains May Be Highly Organized in the Extracellular Matrix

GAGs and proteoglycans can associate to form huge polymeric complexes in the extracellular matrix. Molecules of aggrecan, for example, the major proteoglycan in cartilage (see [Figure 19-40](#)), assemble with hyaluronan in the extracellular space to form aggregates that are as big as a bacterium ([Figure 19-41](#)).

Moreover, besides associating with one another, GAGs and proteoglycans associate with fibrous matrix proteins such as collagen and with protein meshworks such as the basal lamina, creating extremely complex structures. Decorin, which binds to collagen fibrils, is essential for collagen fiber formation; mice that cannot make decorin have fragile skin that has reduced tensile strength. The arrangement of proteoglycan molecules in living tissues is generally hard to determine. As the molecules are highly water-soluble, they may be washed out of the extracellular matrix when tissue sections are exposed to aqueous solutions during fixation. In addition, changes in pH, ionic, or osmotic conditions can drastically alter their conformation. Thus, specialized methods must be used to visualize them in tissues ([Figure 19-42](#)). [↑ TOP](#)

Cell-Surface Proteoglycans Act as Co-receptors

Not all proteoglycans are secreted components of the extracellular matrix. Some are integral components of plasma membranes and have their core protein either inserted across the lipid bilayer or attached to the lipid bilayer by a glycosylphosphatidylinositol (GPI) anchor. Some of these plasma membrane proteoglycans act as *co-receptors* that collaborate with conventional cell-surface receptor proteins, in both binding cells to the extracellular matrix and initiating the response of cells to some extracellular signal proteins. In addition, some conventional receptors have one or more GAG chains and are therefore proteoglycans themselves.

Among the best-characterized plasma membrane proteoglycans are the *syndecans*, which have a membrane-spanning core protein. The extracellular domains of these transmembrane proteoglycans carry up to three chondroitin sulfate and heparan sulfate GAG chains, while their intracellular domains are thought to interact with the actin cytoskeleton in the cell cortex.

Syndecans are located on the surface of many types of cells, including fibroblasts and epithelial cells, where they serve as receptors for matrix proteins. In fibroblasts, syndecans can be found in focal adhesions, where they modulate integrin function by interacting with fibronectin on the cell surface and with cytoskeletal and signaling proteins inside the cell. Syndecans also bind FGFs and present them to FGF receptor proteins on the same cell. Similarly, another plasma membrane proteoglycan, called *betaglycan*, binds TGF- β and may present it to TGF- β receptors.

The importance of proteoglycans as co-receptors is illustrated by the severe developmental defects that can occur when specific proteoglycans are inactivated by mutation. In *Drosophila*, for example, signaling by the secreted signal protein *Wingless* depends on the protein's binding to a specific heparan sulfate proteoglycan co-receptor called *Dally* on the target cell. In mutant flies deficient in Dally, Wingless signaling fails, and the severe developmental defects that result are similar to those that result from mutations in the *wingless* gene itself. In some tissues, inactivation of Dally also inhibits signaling by a secreted protein of the TGF- β family called *Decapentaplegic* (*DPP*).

Some of the proteoglycans discussed in this chapter are summarized in [Table 19-4](#).

Collagens Are the Major Proteins of the Extracellular Matrix

The collagens are a family of fibrous proteins found in all multicellular animals. They are secreted by connective tissue cells, as well as by a variety of other cell types. As a major component of skin and bone, they are the most abundant proteins in mammals, constituting 25% of the total protein mass in these animals.

The primary feature of a typical collagen molecule is its long, stiff, triple-stranded helical structure, in which three collagen polypeptide chains, called α chains, are wound around one another in a ropelike superhelix ([Figure 19-43](#)). Collagens are extremely rich in proline and glycine, both of which are important in the formation of the triple-stranded helix. Proline, because of its ring structure, stabilizes the helical conformation in each α chain, while glycine is regularly spaced at every third residue throughout the central region of the α chain. Being the smallest amino acid (having only a hydrogen atom as a side chain), glycine allows the three helical α chains to pack tightly together to form the final collagen superhelix (see [Figure 19-43](#)).

So far, about 25 distinct collagen α chains have been identified, each encoded by a separate gene. Different combinations of these genes are expressed in different tissues. Although in principle more than 10,000 types of triple-stranded collagen molecules could be assembled from various combinations of the 25 or so α chains, only about 20 types of collagen molecules have been found. The main types of collagen found in connective tissues are types I, II, III, V, and XI, type I being the principal collagen of skin and bone and by far the most common. These are the fibrillar collagens, or fibril-forming collagens, with the ropelike structure illustrated in Figure 19-43. After being secreted into the extracellular space, these collagen molecules assemble into higher-order polymers called *collagen fibrils*, which are thin structures (10–300 nm in diameter) many hundreds of micrometers long in mature tissues and clearly visible in electron micrographs (Figure 19-44; see also Figure 19-42). Collagen fibrils often aggregate into larger, cablelike bundles, several micrometers in diameter, which can be seen in the light microscope as *collagen fibers*.

Collagen types IX and XII are called *fibril-associated collagens* because they decorate the surface of collagen fibrils. They are thought to link these fibrils to one another and to other components in the extracellular matrix. Types IV and VII are *network-forming collagens*. Type IV molecules assemble into a feltlike sheet or meshwork that constitutes a major part of mature basal laminae, while type VII molecules form dimers that assemble into specialized structures called *anchoring fibrils*. Anchoring fibrils help attach the basal lamina of multilayered epithelia to the underlying connective tissue and therefore are especially abundant in the skin.

There are also a number of "collagen-like" proteins, including type XVII, which has a transmembrane domain and is found in hemidesmosomes, and type XVIII, which is located in the basal laminae of blood vessels. Cleavage of the C-terminal domain of type XVIII collagen yields a peptide called *endostatin*, which inhibits new blood vessel formation and is therefore being investigated as an anticancer drug. Some of the collagen types discussed in this chapter are listed in Table 19-5.

Many proteins that contain a repeated pattern of amino acids have evolved by duplications of DNA sequences. The fibrillar collagens apparently arose in this way. Thus, the genes that encode the α chains of most of these collagens are very large (up to 44 kilobases in length) and contain about 50 exons. Most of the exons are 54, or multiples of 54, nucleotides long, suggesting that these collagens arose by multiple duplications of a primordial gene containing 54 nucleotides and encoding exactly 6 Gly-X-Y repeats (see Figure 19-43).  **TOP**

Collagens Are Secreted with a Nonhelical Extension at Each End

Individual collagen polypeptide chains are synthesized on membrane-bound

ribosomes and injected into the lumen of the endoplasmic reticulum (ER) as larger precursors, called *pro- α chains*. These precursors not only have the short amino-terminal signal peptide required to direct the nascent polypeptide to the ER, they also have additional amino acids, called *propeptides*, at both their N- and C-terminal ends. In the lumen of the ER, selected prolines and lysines are hydroxylated to form hydroxyproline and hydroxylysine, respectively, and some of the hydroxylysines are glycosylated. Each pro- α chain then combines with two others to form a hydrogen-bonded, triple-stranded, helical molecule known as *procollagen*.

Hydroxylysines and *hydroxyprolines* (Figure 19-45) are infrequently found in other animal proteins, although hydroxyproline is abundant in some proteins in the plant cell wall. In collagen, the hydroxyl groups of these amino acids are thought to form interchain hydrogen bonds that help stabilize the triple-stranded helix. Conditions that prevent proline hydroxylation, such as a deficiency of ascorbic acid (vitamin C), have serious consequences. In *scurvy*, the disease caused by a dietary deficiency of vitamin C that was common in sailors until the nineteenth century, the defective pro- α chains that are synthesized fail to form a stable triple helix and are immediately degraded within the cell. Consequently, with the gradual loss of the preexisting normal collagen in the matrix, blood vessels become extremely fragile and teeth become loose in their sockets, implying that in these particular tissues the degradation and replacement of collagen occur relatively rapidly. In many other adult tissues, however, the turnover of collagen (and other extracellular matrix macromolecules) is thought to be very slow. In bone, to take an extreme example, collagen molecules persist for about 10 years before they are degraded and replaced. By contrast, most cell proteins have half-lives of hours or days.  [TOP](#)

After Secretion, Fibrillar Procollagen Molecules Are Cleaved to Collagen Molecules, Which Assemble into Fibrils

After secretion, the propeptides of the fibrillar procollagen molecules are removed by specific proteolytic enzymes outside the cell. This converts the procollagen molecules to collagen molecules, which assemble in the extracellular space to form much larger collagen fibrils. The propeptides have at least two functions. First, they guide the intracellular formation of the triple-stranded collagen molecules. Second, because they are removed only after secretion, they prevent the intracellular formation of large collagen fibrils, which could be catastrophic for the cell.

The process of fibril formation is driven, in part, by the tendency of the collagen molecules, which are more than a thousandfold less soluble than procollagen molecules, to self-assemble. The fibrils begin to form close to the cell surface, often in deep infoldings of the plasma membrane formed by the fusion of secretory vesicles with the cell surface. The underlying cortical cytoskeleton can therefore influence the sites, rates, and orientation of fibril

assembly.

When viewed in an electron microscope, collagen fibrils have characteristic cross-striations every 67 nm, reflecting the regularly staggered packing of the individual collagen molecules in the fibril. After the fibrils have formed in the extracellular space, they are greatly strengthened by the formation of covalent cross-links between lysine residues of the constituent collagen molecules (Figure 19-46). The types of covalent bonds involved are found only in collagen and elastin. If cross-linking is inhibited, the tensile strength of the fibrils is drastically reduced; collagenous tissues become fragile, and structures such as skin, tendons, and blood vessels tend to tear. The extent and type of cross-linking vary from tissue to tissue. Collagen is especially highly cross-linked in the Achilles tendon, for example, where tensile strength is crucial.

Figure 19-47 summarizes the various steps in the synthesis and assembly of collagen fibrils. Given the large number of enzymatic steps involved, it is not surprising that there are many human genetic diseases that affect fibril formation. Mutations affecting type I collagen cause *osteogenesis imperfecta*, characterized by weak bones that fracture easily. Mutations affecting type II collagen cause *chondrodysplasias*, characterized by abnormal cartilage, which leads to bone and joint deformities. Mutations affecting type III collagen cause *Ehlers-Danlos syndrome*, characterized by fragile skin and blood vessels and hypermobile joints. [↑ TOP](#)

Fibril-associated Collagens Help Organize the Fibrils

In contrast to GAGs, which resist compressive forces, collagen fibrils form structures that resist tensile forces. The fibrils have various diameters and are organized in different ways in different tissues. In mammalian skin, for example, they are woven in a wickerwork pattern so that they resist tensile stress in multiple directions. In tendons, they are organized in parallel bundles aligned along the major axis of tension. In mature bone and in the cornea, they are arranged in orderly plywoodlike layers, with the fibrils in each layer lying parallel to one another but nearly at right angles to the fibrils in the layers on either side. The same arrangement occurs in tadpole skin (Figure 19-48).

The connective tissue cells themselves must determine the size and arrangement of the collagen fibrils. The cells can express one or more genes for the different types of fibrillar procollagen molecules. But even fibrils composed of the same mixture of fibrillar collagen molecules have different arrangements in different tissues. How is this achieved? Part of the answer is that cells can regulate the disposition of the collagen molecules after secretion by guiding collagen fibril formation in close association with the plasma membrane (see Figure 19-46). In addition, as the spatial organization of collagen fibrils at least partly reflects their interactions with other molecules in the matrix, cells can influence this organization by secreting, along with their fibrillar collagens, different kinds and amounts of other matrix

macromolecules.

Fibril-associated collagens, such as types IX and XII collagens, are thought to be especially important in this regard. They differ from fibrillar collagens in several ways.

1. Their triple-stranded helical structure is interrupted by one or two short nonhelical domains, which makes the molecules more flexible than fibrillar collagen molecules.
2. They are not cleaved after secretion and therefore retain their propeptides.
3. They do not aggregate with one another to form fibrils in the extracellular space. Instead, they bind in a periodic manner to the surface of fibrils formed by the fibrillar collagens. Type IX molecules bind to type-II-collagen-containing fibrils in cartilage, the cornea, and the vitreous of the eye ([Figure 19-49](#)), whereas type XII molecules bind to type-I-collagen-containing fibrils in tendons and various other tissues.

Fibril-associated collagens are thought to mediate the interactions of collagen fibrils with one another and with other matrix macromolecules. In this way, they have a role in determining the organization of the fibrils in the matrix. [↑ TOP](#)

Cells Help Organize the Collagen Fibrils They Secrete by Exerting Tension on the Matrix

Cells interact with the extracellular matrix mechanically as well as chemically, with dramatic effects on the architecture of the tissue. Thus, for example, fibroblasts work on the collagen they have secreted, crawling over it and tugging on it—helping to compact it into sheets and draw it out into cables. When fibroblasts are mixed with a meshwork of randomly oriented collagen fibrils that form a gel in a culture dish, the fibroblasts tug on the meshwork, drawing in collagen from their surroundings and thereby causing the gel to contract to a small fraction of its initial volume. By similar activities, a cluster of fibroblasts surrounds itself with a capsule of densely packed and circumferentially oriented collagen fibers.

If two small pieces of embryonic tissue containing fibroblasts are placed far apart on a collagen gel, the intervening collagen becomes organized into a compact band of aligned fibers that connect the two explants ([Figure 19-50](#)). The fibroblasts subsequently migrate out from the explants along the aligned collagen fibers. Thus, the fibroblasts influence the alignment of the collagen fibers, and the collagen fibers in turn affect the distribution of the fibroblasts. Fibroblasts presumably have a similar role in generating long-range order in the extracellular matrix inside the body—in helping to create tendons and

ligaments, for example, and the tough, dense layers of connective tissue that ensheath and bind together most organs. [↑ TOP](#)

Elastin Gives Tissues Their Elasticity

Many vertebrate tissues, such as skin, blood vessels, and lungs, need to be both strong and elastic in order to function. A network of **elastic fibers** in the extracellular matrix of these tissues gives them the required resilience so that they can recoil after transient stretch ([Figure 19-51](#)). Elastic fibers are at least five times more extensible than a rubber band of the same cross-sectional area. Long, inelastic collagen fibrils are interwoven with the elastic fibers to limit the extent of stretching and prevent the tissue from tearing.

The main component of elastic fibers is elastin, a highly hydrophobic protein (about 750 amino acids long), which, like collagen, is unusually rich in proline and glycine but, unlike collagen, is not glycosylated and contains some hydroxy-proline but no hydroxylysine. Soluble *tropoelastin* (the biosynthetic precursor of elastin) is secreted into the extracellular space and assembled into elastic fibers close to the plasma membrane, generally in cell-surface infoldings. After secretion, the tropoelastin molecules become highly cross-linked to one another, generating an extensive network of elastin fibers and sheets. The cross-links are formed between lysines by a mechanism similar to the one discussed earlier that operates in cross-linking collagen molecules.

The elastin protein is composed largely of two types of short segments that alternate along the polypeptide chain: hydrophobic segments, which are responsible for the elastic properties of the molecule; and alanine- and lysine-rich α -helical segments, which form cross-links between adjacent molecules. Each segment is encoded by a separate exon. There is still controversy, however, concerning the conformation of elastin molecules in elastic fibers and how the structure of these fibers accounts for their rubberlike properties. In one view, the elastin polypeptide chain, like the polymer chains in ordinary rubber, adopts a loose "random coil" conformation, and it is the random coil structure of the component molecules cross-linked into the elastic fiber network that allows the network to stretch and recoil like a rubber band ([Figure 19-52](#)).

Elastin is the dominant extracellular matrix protein in arteries, comprising 50% of the dry weight of the largest artery—the aorta. Mutations in the elastin gene causing a deficiency of the protein in mice or humans result in narrowing of the aorta or other arteries as a result of excessive proliferation of smooth muscle cells in the arterial wall. Apparently, the normal elasticity of an artery is required to restrain the proliferation of these cells.

Elastic fibers are not composed solely of elastin. The elastin core is covered with a sheath of *microfibrils*, each of which has a diameter of about 10 nm. Microfibrils are composed of a number of distinct glycoproteins, including the

large glycoprotein *fibrillin*, which binds to elastin and is essential for the integrity of elastic fibers. Mutations in the fibrillin gene result in *Marfan's syndrome*, a relatively common human genetic disease affecting connective tissues that are rich in elastic fibers; in the most severely affected individuals, the aorta is prone to rupture. Microfibrils are thought to be important in the assembly of elastic fibers. They appear before elastin in developing tissues and seem to form a scaffold on which the secreted elastin molecules are deposited. As the elastin is deposited, the microfibrils become displaced to the periphery of the growing fiber. [↑ TOP](#)

Fibronectin Is an Extracellular Protein That Helps Cells Attach to the Matrix

The extracellular matrix contains a number of noncollagen proteins that typically have multiple domains, each with specific binding sites for other matrix macromolecules and for receptors on the surface of cells. These proteins therefore contribute to both organizing the matrix and helping cells attach to it. The first of them to be well characterized was fibronectin, a large glycoprotein found in all vertebrates. Fibronectin is a dimer composed of two very large subunits joined by disulfide bonds at one end. Each subunit is folded into a series of functionally distinct domains separated by regions of flexible polypeptide chain ([Figure 19-53A](#) and [B](#)). The domains in turn consist of smaller modules, each of which is serially repeated and usually encoded by a separate exon, suggesting that the fibronectin gene, like the collagen genes, evolved by multiple exon duplications. All forms of fibronectin are encoded by a single large gene that contains about 50 exons of similar size. Transcription produces a single large RNA molecule that can be alternatively spliced to produce the various isoforms of fibronectin. The main type of module, called the **type III fibronectin repeat**, binds to integrins. It is about 90 amino acids long and occurs at least 15 times in each subunit. The type III fibronectin repeat is among the most common of all protein domains in vertebrates.

One way to analyze a complex multifunctional protein molecule like fibronectin is to chop it into pieces and determine the function of its individual domains. When fibronectin is treated with a low concentration of a proteolytic enzyme, the polypeptide chain is cut in the connecting regions between the domains, leaving the domains themselves intact. One can then show that one of its domains binds to collagen, another to heparin, another to specific receptors on the surface of various types of cells, and so on (see [Figure 19-53B](#)). Synthetic peptides corresponding to different segments of the cell-binding domain have been used to identify a specific tripeptide sequence (*Arg-Gly-Asp*, or *RGD*), which is found in one of the type III repeats (see [Figure 19-53C](#)), as a central feature of the binding site. Even very short peptides containing this **RGD sequence** can compete with fibronectin for the binding site on cells, thereby inhibiting the attachment of the cells to a fibronectin matrix. If these peptides are coupled to a solid surface, they cause cells to adhere to it.

The RGD sequence is not confined to fibronectin. It is found in a number of extracellular proteins, including, for example, the blood-clotting factor *fibrinogen*. Fibrinogen peptides containing this RGD sequence have been useful in the development of anti-clotting drugs that mimic these peptides. Snakes use a similar strategy to cause their victims to bleed: they secrete RGD-containing anti-clotting proteins called *disintegrins* into their venom.

RGD sequences are recognized by several members of the integrin family of cell-surface matrix receptors. Each integrin, however, specifically recognizes its own small set of matrix molecules, indicating that tight binding requires more than just the RGD sequence. [↑ TOP](#)

Fibronectin Exists in Both Soluble and Fibrillar Forms

There are multiple isoforms of fibronectin. One, called *plasma fibronectin*, is soluble and circulates in the blood and other body fluids, where it is thought to enhance blood clotting, wound healing, and phagocytosis. All of the other forms assemble on the surface of cells and are deposited in the extracellular matrix as highly insoluble *fibronectin fibrils*. In these cell-surface and matrix forms, fibronectin dimers are cross-linked to one another by additional disulfide bonds.

Unlike fibrillar collagen molecules, which can be made to self-assemble into fibrils in a test tube, fibronectin molecules assemble into fibrils only on the surface of certain cells. This is because additional proteins are needed for fibril formation, especially fibronectin-binding integrins. In the case of fibroblasts, fibronectin fibrils are associated with integrins at sites called *fibrillar adhesions*. These are distinct from focal adhesions, in that they are more elongated and contain different intracellular anchor proteins. The fibronectin fibrils on the cell surface are highly stretched and under tension. The tension is exerted by the cell and is essential for fibril formation, as we discuss below. Some secreted proteins function to prevent fibronectin assembly in inappropriate places. *Uteroglobin*, for example, binds to fibronectin and prevents it from forming fibrils in the kidney. Mice that have a mutation in the uteroglobin gene accumulate insoluble fibronectin fibrils in their kidneys.

The importance of fibronectin in animal development is dramatically demonstrated by gene inactivation experiments. Mutant mice that are unable to make fibronectin die early in embryogenesis because their endothelial cells fail to form proper blood vessels. This defect is thought to result from abnormalities in the interactions of these cells with the surrounding extracellular matrix, which normally contains fibronectin. [↑ TOP](#)

Intracellular Actin Filaments Regulate the Assembly of Extracellular Fibronectin Fibrils

The fibronectin fibrils that form on or near the surface of fibroblasts are usually aligned with adjacent intracellular actin stress fibers ([Figure 19-54](#)). In fact, intracellular actin filaments promote the assembly of secreted fibronectin molecules into fibrils and influence fibril orientation. If cells are treated with the drug cytochalasin, which disrupts actin filaments, the fibronectin fibrils dissociate from the cell surface (just as they do during mitosis when a cell rounds up).

The interactions between extracellular fibronectin fibrils and intracellular actin filaments across the fibroblast plasma membrane are mediated mainly by integrin transmembrane adhesion proteins. The contractile actin and myosin cytoskeleton thereby pulls on the fibronectin matrix to generate tension. As a result, the fibronectin fibrils are stretched, exposing a cryptic (hidden) binding site in the fibronectin molecules that allows them to bind directly to one another. In addition, the stretching exposes more binding sites for integrins. In this way, the actin cytoskeleton promotes fibronectin polymerization and matrix assembly.

Extracellular signals can regulate the assembly process by altering the actin cytoskeleton and thereby the tension on the fibrils. Many other extracellular matrix proteins have multiple repeats similar to the type III fibronectin repeat, and it is possible that tension exerted on these proteins also uncovers cryptic binding sites and thereby influences their polymerization. [↑ TOP](#)

Glycoproteins in the Matrix Help Guide Cell Migration

Fibronectin is important not only for cell adhesion to the matrix but also for guiding cell migrations in vertebrate embryos. Large amounts of fibronectin, for example, are found along the pathway followed by migrating prospective mesodermal cells during amphibian gastrulation (discussed in [Chapter 21](#)). Although all cells of the early embryo can attach to fibronectin, only these migrating cells can spread and migrate on fibronectin. The migration is inhibited by an injection into the developing amphibian embryo of various ligands that disrupt the ability of the cells to bind to fibronectin.

Many matrix proteins are believed to have a role in guiding cell movements during development. The *tenascins* and *thrombospondins*, for example, are composed of several types of short amino acid sequences that are repeated many times and form functionally distinct domains. They can either promote or inhibit cell adhesion, depending on the cell type. Indeed, anti-adhesive interactions are as important as adhesive ones in guiding cell migration, as we discuss in [Chapter 21](#). [↑ TOP](#)

Basal Laminae Are Composed Mainly of Type IV Collagen, Laminin, Nidogen, and a Heparan Sulfate Proteoglycan

As mentioned earlier, **basal laminae** are flexible, thin (40–120 nm thick) mats of specialized extracellular matrix that underlie all epithelial cell sheets and tubes. They also surround individual muscle cells, fat cells, and Schwann cells (which wrap around peripheral nerve cell axons to form myelin). The basal lamina thus separates these cells and epithelia from the underlying or surrounding connective tissue. In other locations, such as the kidney glomerulus, a basal lamina lies between two cell sheets and functions as a highly selective filter ([Figure 19-55](#)). Basal laminae have more than simple structural and filtering roles, however. They are able to determine cell polarity, influence cell metabolism, organize the proteins in adjacent plasma membranes, promote cell survival, proliferation, or differentiation, and serve as specific highways for cell migration.

The basal lamina is synthesized largely by the cells that rest on it ([Figure 19-56](#)). In some multilayered epithelia, such as the stratified squamous epithelium that forms the epidermis of the skin, the basal lamina is tethered to the underlying connective tissue by specialized anchoring fibrils made of type VII collagen molecules. The term *basement membrane* is often used to describe the composite of the basal lamina and this layer of collagen fibrils. In one type of skin disease, these connections are either absent or destroyed, and the epidermis and its basal lamina become detached from the underlying connective tissue, causing blistering.

Although its precise composition varies from tissue to tissue and even from region to region in the same lamina, most mature basal laminae contain *type IV collagen*, the large heparan sulfate proteoglycan perlecan, and the glycoproteins laminin and nidogen (also called entactin).

Type IV collagens exist in several isoforms. They all have a more flexible structure than the fibrillar collagens; their triple-stranded helix is interrupted in 26 regions, allowing multiple bends. They are not cleaved after secretion, but interact via their uncleaved terminal domains to assemble extracellularly into a flexible, sheetlike, multilayered network.

Early in development, basal laminae contain little or no type IV collagen and consist mainly of laminin molecules. **Laminin-1** (classical laminin) is a large, flexible protein composed of three very long polypeptide chains (α , β , and γ) arranged in the shape of an asymmetric cross and held together by disulfide bonds ([Figure 19-57](#)). Several isoforms of each type of chain can associate in different combinations to form a large family of laminins. The laminin γ -1 chain is a component of most laminin heterotrimers, and mice lacking it die during embryogenesis because they are unable to make a basal lamina. Like many other proteins in the extracellular matrix, the laminin in basement membranes consists of several functional domains: one binds to *perlecan*, one to *nidogen*, and two or more to laminin receptor proteins on the surface of cells.

Like type IV collagen, laminins can self-assemble *in vitro* into a feltlike sheet,

largely through interactions between the ends of the laminin arms. As nidogen and perlecan can bind to both laminin and type IV collagen, it is thought that they connect the type IV collagen and laminin networks ([Figure 19-58](#)). In tissues, laminins and type IV collagen preferentially polymerize while bound to receptors on the surface of the cells producing the proteins. Many of the cell-surface receptors for type IV collagen and laminin are members of the integrin family. Another important type of laminin receptor is the transmembrane protein *dystroglycan*, which, together with integrins, may organize the assembly of the basal lamina.

The shapes and sizes of some of the extracellular matrix molecules discussed in this chapter are compared in [Figure 19-59](#). [↑ TOP](#)

Basal Laminae Perform Diverse Functions

As we have mentioned, in the kidney glomerulus, an unusually thick basal lamina acts as a molecular filter, preventing the passage of macromolecules from the blood into the urine as urine is formed (see [Figure 19-55](#)). The heparan sulfate proteoglycan in the basal lamina seems to be important for this function: when its GAG chains are removed by specific enzymes, the filtering properties of the lamina are destroyed. Type IV collagen also has a role, as a human hereditary kidney disorder (*Alport syndrome*) results from mutations in type IV collagen α -chain genes.

The basal lamina can also act as a selective barrier to the movement of cells. The lamina beneath an epithelium, for example, usually prevents fibroblasts in the underlying connective tissue from making contact with the epithelial cells. It does not, however, stop macrophages, lymphocytes, or nerve processes from passing through it. The basal lamina is also important in tissue regeneration after injury. When tissues such as muscles, nerves, and epithelia are damaged, the basal lamina survives and provides a scaffold along which regenerating cells can migrate. In this way, the original tissue architecture is readily reconstructed. In some cases, as in the skin or cornea, the basal lamina becomes chemically altered after injury—for example, by the addition of fibronectin, which promotes the cell migration required for wound healing.

A particularly striking example of the instructive role of the basal lamina in regeneration comes from studies on the *neuromuscular junction*, the site where the nerve terminals of a motor neuron form a chemical synapse with a skeletal muscle cell (discussed in [Chapter 11](#)). The basal lamina that surrounds the muscle cell separates the nerve and muscle cell plasma membranes at the synapse, and the synaptic region of the lamina has a distinctive chemical character, with special isoforms of type IV collagen and laminin and a heparan sulfate proteoglycan called **agrin**.

This basal lamina at the synapse has a central role in reconstructing the synapse after nerve or muscle injury. If a frog muscle and its motor nerve are

destroyed, the basal lamina around each muscle cell remains intact and the sites of the old neuromuscular junctions are still recognizable. If the motor nerve, but not the muscle, is allowed to regenerate, the nerve axons seek out the original synaptic sites on the empty basal lamina and differentiate there to form normal-looking nerve terminals. Thus, the junctional basal lamina by itself can guide the regeneration of motor nerve terminals.

Similar experiments show that the basal lamina also controls the localization of the acetylcholine receptors that cluster in the muscle cell plasma membrane at a neuromuscular junction. If the muscle and nerve are both destroyed, but now the muscle is allowed to regenerate while the nerve is prevented from doing so, the acetylcholine receptors synthesized by the regenerated muscle localize predominantly in the region of the old junctions, even though the nerve is absent ([Figure 19-60](#)). Thus, the junctional basal lamina apparently coordinates the local spatial organization of the components in each of the two cells that form a neuromuscular junction. Some of the matrix proteins have been identified. Motor neuron axons, for example, deposit agrin in the junctional basal lamina, where it triggers the assembly of acetylcholine receptors and other proteins in the junctional plasma membrane of the muscle cell. Conversely, muscle cells deposit a particular isoform of laminin in the junctional basal lamina. Both agrin and this isoform of laminin are essential for the formation of normal neuromuscular junctions. [↑ TOP](#)

The Extracellular Matrix Can Influence Cell Shape, Cell Survival, and Cell Proliferation

The extracellular matrix can influence the organization of a cell's cytoskeleton. This can be vividly demonstrated by using transformed (cancerlike) fibroblasts in culture (discussed in [Chapter 23](#)). Transformed cells often make less fibronectin than normal cultured cells and behave differently. They adhere poorly to the culture substratum, for example, and fail to flatten out or develop the organized intracellular bundles of actin filaments known as *stress fibers*. The decrease in fibronectin production and adhesion may contribute to the tendency of cancer cells to break away from the primary tumor and spread to other parts of the body.

In some cases, fibronectin deficiency seems also to be at least partly responsible for this abnormal morphology of cancer cells: if the cells are grown on a matrix of organized fibronectin fibrils, they flatten out and assemble intracellular stress fibers that are aligned with the extracellular fibronectin fibrils. This interaction between the extracellular matrix and the cytoskeleton is reciprocal in that intracellular actin filaments can promote the assembly and influence the orientation of fibronectin fibrils, as described earlier. Since the cytoskeleton can exert forces that orient the matrix macromolecules the cell secretes and the matrix macromolecules can in turn organize the cytoskeleton of the cells they contact, the extracellular matrix can in principle propagate order from cell to cell ([Figure 19-61](#)), creating large-

scale oriented structures, as described earlier (see [Figure 19-50](#)). The integrins serve as the main adaptors in this ordering process, mediating the interactions between cells and the matrix around them.

Most cells need to attach to the extracellular matrix to grow and proliferate—and, in many cases, even to survive. This dependence of cell growth, proliferation, and survival on attachment to a substratum is known as anchorage dependence, and it is mediated mainly by integrins and the intracellular signals they generate. The physical spreading of a cell on the matrix also has a strong influence on intracellular events. Cells that are forced to spread over a large surface area survive better and proliferate faster than cells that are not so spread out, even if in both cases the cells have the same area making contact with the matrix directly ([Figure 19-62](#)). This stimulatory effect of cell spreading presumably helps tissues to regenerate after injury. If cells are lost from an epithelium, for example, the spreading of the remaining cells into the vacated space will stimulate them to proliferate until they fill the gap. It is still uncertain, however, how a cell senses its extent of spreading so as to adjust its behavior accordingly. [↑ TOP](#)

The Controlled Degradation of Matrix Components Helps Cells Migrate

The regulated turnover of extracellular matrix macromolecules is crucial to a variety of important biological processes. Rapid degradation occurs, for example, when the uterus involutes after childbirth, or when the tadpole tail is resorbed during metamorphosis (see [Figure 17-36](#)). A more localized degradation of matrix components is required when cells migrate through a basal lamina. This occurs when white blood cells migrate across the basal lamina of a blood vessel into tissues in response to infection or injury, and when cancer cells migrate from their site of origin to distant organs via the bloodstream or lymphatic vessels—the process known as *metastasis*. Even in the seemingly static extracellular matrix of adult animals, there is a slow, continuous turnover, with matrix macromolecules being degraded and resynthesized.

In each of these cases, matrix components are degraded by extracellular proteolytic enzymes (proteases) that are secreted locally by cells. Thus, antibodies that recognize the products of proteolytic cleavage stain matrix only around cells. Many of these proteases belong to one of two general classes. Most are **matrix metalloproteases**, which depend on bound Ca^{2+} or Zn^{2+} for activity; the others are serine proteases, which have a highly reactive serine in their active site. Together, metalloproteases and serine proteases cooperate to degrade matrix proteins such as collagen, laminin, and fibronectin. Some metalloproteases, such as the *collagenases*, are highly specific, cleaving particular proteins at a small number of sites. In this way, the structural integrity of the matrix is largely retained, but cell migration can be greatly facilitated by the small amount of proteolysis. Other metalloproteases may be

less specific, but, because they are anchored to the plasma membrane, they can act just where they are needed.

The importance of proteolysis in cell migration can be shown by using protease inhibitors, which often block migration. Moreover, cells that migrate readily on type I collagen in culture can no longer do so if the collagen is made resistant to proteolysis by mutating the collagenase-sensitive cleavage sites. The proteolysis of matrix proteins can contribute to cell migration in several ways: (1) it can simply clear a path through the matrix; (2) it can expose cryptic sites on the cleaved proteins that promote cell binding, cell migration, or both; (3) it can promote cell detachment so that a cell can move onward, or (4) it can release extracellular signal proteins that stimulate cell migration.

Three basic mechanisms operate to ensure that the proteases that degrade the matrix components are tightly controlled.

Local activation: Many proteases are secreted as inactive precursors that can be activated locally when needed. An example is *plasminogen*, an inactive protease precursor that is abundant in the blood. It is cleaved locally by other proteases called *plasminogen activators* to yield the active serine protease *plasmin*, which helps break up blood clots. *Tissue-type plasminogen activator (tPA)* is often given to patients who have just had a heart attack or thrombotic stroke; it helps dissolve the arterial clot that caused the attack, thereby restoring bloodflow to the tissue.

Confinement by cell-surface receptors: Many cells have receptors on their surface that bind proteases, thereby confining the enzyme to the sites where it is needed. A second type of plasminogen activator called *urokinase-type plasminogen activator (uPA)* is an example. It is found bound to receptors on the growing tips of axons and at the leading edge of some migrating cells, where it may serve to clear a pathway for their migration. Receptor-bound uPA may also help some cancer cells metastasize ([Figure 19-63](#)).

Secretion of inhibitors: The action of proteases is confined to specific areas by various secreted protease inhibitors, including the *tissue inhibitors of metalloproteases (TIMPs)* and the serine protease inhibitors known as *serpins*. These inhibitors are protease-specific and bind tightly to the activated enzyme, blocking its activity. An attractive idea is that the inhibitors are secreted by cells at the margins of areas of active protein degradation in order to protect uninvolved matrix; they may also protect cell-surface proteins required for cell adhesion and migration. The overexpression of TIMPs inhibits the migration of some cell types, indicating the importance of metalloproteases for the migration. [↑ TOP](#)

Summary

Cells in connective tissues are embedded in an intricate extracellular matrix

that not only binds the cells together but also influences their survival, development, shape, polarity, and behavior. The matrix contains various protein fibers interwoven in a hydrated gel composed of a network of glycosaminoglycan (GAG) chains.

GAGs are a heterogeneous group of negatively charged polysaccharide chains that (except for hyaluronan) are covalently linked to protein to form proteoglycan molecules. They occupy a large volume and form hydrated gels in the extracellular space. Proteoglycans are also found on the surface of cells, where they function as co-receptors to help cells respond to secreted signal proteins.

Fiber-forming proteins strengthen the matrix and give it form. They also provide surfaces for cells to adhere to. Elastin molecules form an extensive cross-linked network of fibers and sheets that can stretch and recoil, imparting elasticity to the matrix. The fibrillar collagens (types I, II, III, V, and XI) are ropelike, triple-stranded helical molecules that aggregate into long fibrils in the extracellular space. The fibrils in turn can assemble into a variety of highly ordered arrays. Fibril-associated collagen molecules, such as types IX and XII, decorate the surface of collagen fibrils and influence the interactions of the fibrils with one another and with other matrix components.

In contrast, type IV collagen molecules assemble into a sheetlike meshwork that is a crucial component of all mature basal laminae. All basal laminae are based on a mesh of laminin molecules. The collagen and laminin networks in mature basal laminae are bridged by the protein nidogen and the large heparan sulfate proteoglycan perlecan. Fibronectin and laminin are examples of large, multidomain matrix glycoproteins. By means of their multiple binding domains, such proteins help organize the matrix and help cells adhere to it.

Matrix proteins such as collagens, laminins, and fibronectin are assembled into fibrils or networks on the surface of the cells that produce them by a process that depends on the underlying actin cortex. The organization of the matrix can reciprocally influence the organization of the cell's cytoskeleton and can mechanically influence cell spreading. The matrix also influences cell behavior by binding to cell-surface receptors that activate intracellular signaling pathways.

Matrix components are degraded by extracellular proteolytic enzymes. Most of these are matrix metalloproteases, which depend on bound Ca^{2+} or Zn^{2+} for activity, while others are serine proteases, which have a reactive serine in their active site. Various mechanisms operate to ensure that the degradation of matrix components is tightly controlled. Cells can, for example, cause a localized degradation of matrix components to clear a path through the matrix. [↑ TOP](#)

Figure 19-39. The linkage between a GAG chain and its core protein in a proteoglycan molecule. A specific link tetrasaccharide is first assembled on a serine side chain. In most cases, it is unclear how the particular serine is selected, but it seems that a specific local conformation of the polypeptide chain, rather than a specific linear sequence of amino acids, is recognized. The rest of the GAG chain, consisting mainly of a repeating disaccharide unit, is then synthesized, with one sugar being added at a time. In chondroitin sulfate, the disaccharide is composed of d-glucuronic acid and *N*-acetyl-d-galactosamine; in heparan sulfate, it is d-glucosamine (or l-iduronic acid) and *N*-acetyl-d-glucosamine; in keratan sulfate, it is d-galactose and *N*-acetyl-d-glucosamine.

Figure 19-40. Examples of a small (decorin) and a large (aggrecan) proteoglycan found in the extracellular matrix.

These two proteoglycans are compared with a typical secreted glycoprotein molecule, pancreatic ribonuclease B. All three are drawn to scale. The core proteins of both aggrecan and decorin contain oligosaccharide chains as well as the GAG chains, but these are not shown. Aggrecan typically consists of about 100 chondroitin sulfate chains and about 30 keratan sulfate chains linked to a serine-rich core protein of almost 3000 amino acids. Decorin "decorates" the surface of collagen fibrils, hence its name.

Figure 19-41. An aggrecan aggregate from fetal bovine cartilage. (A) An electron micrograph of an aggrecan aggregate shadowed with platinum. Many free aggrecan molecules are also visible. (B) A drawing of the giant aggrecan aggregate shown in (A). It consists of about 100 aggrecan monomers (each like the one shown in [Figure 19-40](#)) noncovalently bound to a single hyaluronan chain through two link proteins that bind both to the core protein of the proteoglycan and to the hyaluronan chain, thereby stabilizing the aggregate. The link proteins are members of a family of hyaluronan-binding proteins, some of which are cell-surface proteins. The molecular weight of such a complex can be 10^8 or more, and it occupies a volume equivalent to that of a bacterium, which is about $2 \times 10^{-12} \text{ cm}^3$. Figure 19-42. Proteoglycans in the extracellular matrix of rat cartilage. The tissue was rapidly frozen at -196°C , and fixed and stained while still frozen (a process called freeze substitution) to prevent the GAG chains from collapsing. In this electron micrograph, the proteoglycan molecules are seen to form a fine filamentous network in which a single striated collagen fibril is embedded. The more darkly stained parts of the proteoglycan molecules are the core proteins; the faintly stained threads are the GAG chains. (Reproduced from E.B. Hunziker and R.K. Schenk, *J. Figure 19-43. The structure of a typical collagen molecule. (A) A model of part of a single collagen α chain in which each amino acid is represented by a sphere. The chain is about 1000 amino acids long. It is arranged as a left-handed helix, with three amino acids per turn and with glycine as every third amino acid. Therefore, an α chain is composed of a series of triplet Gly-X-Y sequences, in which X and Y can be any amino acid (although X is commonly proline and Y is commonly hydroxyproline). (B) A model of part of a collagen molecule in which three α chains, each shown in a different color, are wrapped around one another to form a triple-stranded helical rod. Glycine is the only

amino acid small enough to occupy the crowded interior of the triple helix.
Only a short length of the molecule is shown; the entire molecule is 300 nm long. (From model by B.L. Trus.)

Figure 19-46. Cross-links formed between modified lysine side chains within a collagen fibril. Covalent intramolecular and intermolecular cross-links are formed in several steps. First, certain lysines and hydroxylysines are deaminated by the extracellular enzyme lysyl oxidase to yield highly reactive aldehyde groups. The aldehydes then react spontaneously to form covalent bonds with each other or with other lysines or hydroxylysines. Most of the cross-links form between the short nonhelical segments at each end of the collagen molecules.

Figure 19-53. The structure of a fibronectin dimer. (A) Electron micrographs of individual fibronectin dimer molecules shadowed with platinum; red arrows mark the C-termini. (B) The two polypeptide chains are similar but generally not identical (being made from the same gene but from differently spliced mRNAs). They are joined by two disulfide bonds near the C-termini. Each chain is almost 2500 amino acids long and is folded into five or six domains connected by flexible polypeptide segments. Individual domains are specialized for binding to a particular molecule or to a cell, as indicated for five of the domains. For simplicity, not all of the known binding sites are shown (there are other cell-binding sites, for example). (C) The three-dimensional structure of two type III fibronectin repeats as determined by x-ray crystallography. The type III repeat is the main repeating module in fibronectin. Both the Arg-Gly-Asp (RGD) and the "synergy" sequences shown in red form part of the major cell-binding site (shown blue in B). (A, from J. Engel et al., *J. Mol. Figure 19-55. Three ways in which basal laminae are organized. Basal laminae (yellow) surround certain cells (such as skeletal muscle cells), underlie epithelia, and are interposed between two cell sheets (as in the kidney glomerulus). Note that, in the kidney glomerulus, both cell sheets have gaps in them, so that the basal lamina serves as the permeability barrier determining which molecules will pass into the urine from the blood.

Figure 19-60. Regeneration experiments demonstrating the special character of the junctional basal lamina at a neuromuscular junction. When the nerve, but not the muscle, is allowed to regenerate after both the nerve and muscle have been damaged (*upper part of figure*), the junctional basal lamina directs the regenerating nerve to the original synaptic site. When the muscle, but not the nerve, is allowed to regenerate (*lower part of figure*), the junctional basal lamina causes newly made acetylcholine receptors (*blue*) to accumulate at the original synaptic site. The muscle regenerates from satellite cells (discussed in [Chapter 22](#)) located between the basal lamina and the original muscle cell (not shown). These experiments show that the junctional basal lamina controls the localization of synaptic components on both sides of the lamina.

Figure 19-63. The importance of proteases bound to cell-surface receptors. (A) Human prostate cancer cells make and secrete the serine protease uPA, which binds to cell-surface uPA receptor proteins. (B) The same cells have been transfected with DNA that encodes an excess of an inactive form of uPA, which binds to the uPA receptors but has no protease activity. By occupying most of the uPA receptors, the inactive uPA prevents the active protease from binding to the cell surface. Both types of cells secrete active uPA, grow rapidly, and produce tumors when injected into experimental animals. But the cells in (A) metastasize widely, whereas the cells in (B) do not. To metastasize via the blood, tumor cells have to crawl through basal laminae and other extracellular matrices on the way into and out of the bloodstream. This experiment suggests that proteases must be cell-surface bound to mediate migration through the matrix.

Integrins

The linkage of the extracellular matrix to the cell requires transmembrane cell adhesion proteins that act as *matrix receptors* and tie the matrix to the cell's cytoskeleton. Although we have seen that some transmembrane proteoglycans function as co-receptors for matrix components, the principal receptors on animal cells for binding most extracellular matrix proteins—including collagens, fibronectin, and laminins—are the integrins. These constitute a large family of homologous transmembrane, cell-matrix adhesion receptors. In blood cells, as we have seen, integrins also serve as cell-cell adhesion molecules, helping the cells bind to other cells, as well as to the extracellular matrix.

Integrins, like other cell adhesion molecules, differ from cell-surface receptors for hormones and for other extracellular soluble signal molecules in that they usually bind their ligand with lower affinity and are usually present at about tenfold to a hundredfold higher concentration on the cell surface. If the binding were too tight, cells would presumably become irreversibly glued to the matrix and would be unable to move—a problem that does not arise if attachment depends on large numbers of weak adhesions. This is an example of the "Velcro principle" mentioned earlier. Like other transmembrane cell adhesion proteins, however, integrins do more than just attach a cell to its surroundings. They also activate intracellular signaling pathways that communicate to the cell the character of the extracellular matrix that is bound.

Integrins Are Transmembrane Heterodimers

Integrins are crucially important because they are the main receptor proteins that cells use to both bind to and respond to the extracellular matrix. An integrin molecule is composed of two noncovalently associated transmembrane glycoprotein subunits called α and β ([Figure 19-64](#); see also [Figure 19-12B](#)). Because the same integrin molecule in different cell types can have different ligand-binding specificities, it seems that additional cell-type-specific factors can interact with integrins to modulate their binding activity.

The binding of integrins to their ligands depends on extracellular divalent

Search

This book
books

All

PubMed

cations (Ca^{2+} or Mg^{2+} , depending on the integrin), reflecting the presence of divalent-cation-binding domains in the extracellular part of the α and β subunits. The type of divalent cation can influence both the affinity and the specificity of the binding of an integrin to its ligands.

Many matrix proteins in vertebrates are recognized by multiple integrins. At least 8 integrins bind fibronectin, for example, and at least 5 bind laminin. A variety of human integrin heterodimers are formed from 9 types of β subunits and 24 types of α subunits. This diversity is further increased by alternative splicing of some integrin RNAs. Some of the best-studied integrins are listed in [Table 19-6](#).

β_1 subunits form dimers with at least 12 distinct α subunits. They are found on almost all vertebrate cells: $\alpha_5\beta_1$, for example, is a fibronectin receptor and $\alpha_6\beta_1$ a laminin receptor on many types of cells. Mutant mice that cannot make any β_1 integrins die at implantation, whereas mice that are only unable to make the α_7 subunit (the partner for β_1 in muscle) survive but develop muscular dystrophy (as do mice that cannot make the laminin ligand for the $\alpha_7\beta_1$ integrin).

The β_2 subunits form dimers with at least four types of α subunit. They are expressed exclusively on the surface of white blood cells, where they have an essential role in enabling these cells to fight infection. The β_2 integrins mainly mediate cell-cell rather than cell-matrix interactions, binding to specific ligands on another cell, such as an endothelial cell. The ligands, sometimes referred to as *counterreceptors*, are members of the Ig superfamily of cell-cell adhesion molecules discussed earlier. The β_2 integrins enable white blood cells, for example, to attach firmly to endothelial cells at sites of infection and migrate out of the bloodstream into the infected site (see [Figure 19-30B](#)). Humans with the genetic disease called *leucocyte adhesion deficiency* are unable to synthesize β_2 subunits. As a consequence, their white blood cells lack the entire family of β_2 receptors, and they suffer repeated bacterial infections.

The β_3 integrins are found on a variety of cells, including blood platelets. They bind several matrix proteins, including fibrinogen. Platelets interact with fibrinogen during blood clotting, and humans with *Glanzmann's disease*, who are genetically deficient in β_3 integrins, bleed excessively. [↑ TOP](#)

Integrins Must Interact with the Cytoskeleton to Bind Cells to the Extracellular Matrix

Integrins function as transmembrane linkers (or "integrators"), mediating the interactions between the cytoskeleton and the extracellular matrix that are required for cells to grip the matrix. Most integrins are connected to bundles of actin filaments. The $\alpha_6\beta_4$ integrin found in hemidesmosomes is an exception: it is connected to intermediate filaments. After the binding of a typical integrin to its ligand in the matrix, the cytoplasmic tail of the β subunit binds to several intracellular anchor proteins, including talin, α -actinin, and filamin. These anchor proteins can bind directly to actin or to other anchor proteins such as vinculin, thereby linking the integrin to actin filaments in the cell cortex. Given the right conditions, this linkage leads to a clustering of the integrins and the formation of focal adhesions between the cell and the extracellular matrix, as discussed earlier.

If the cytoplasmic domain of the β subunit is deleted using recombinant DNA techniques, the shortened integrins still bind to their ligands, but they no longer mediate robust adhesion, and they fail to cluster at focal adhesions. It seems that integrins must interact with the cytoskeleton to bind cells strongly to the matrix, just as cadherins must interact with the cytoskeleton to hold cells together efficiently. The cytoskeletal attachment may help cluster the integrins, providing a stronger aggregate bond; it may also lock the integrin in a conformation that allows the integrin to bind its ligand more tightly.

Just as cadherins can promote cell-cell adhesion without forming mature adherens junctions, integrins can mediate cell-matrix adhesion without forming mature focal adhesions. In both cases, however, the transmembrane adhesion proteins may still bind to the cytoskeleton. For integrins, this kind of adhesion occurs when cells are spreading or migrating, and it results in the formation of *focal complexes*. For such focal complexes to mature into the focal adhesions that are typical of many well-spread cells, the activation of the small GTPase Rho is required. The activation of Rho leads to the recruitment of more actin filaments and integrins to the contact site (discussed in [Chapter 16](#)). [↑ TOP](#)

Cells Can Regulate the Activity of Their Integrins

We discuss below how integrin clustering activates intracellular signaling pathways. But signaling also operates in the opposite direction: signals generated inside the cell can either enhance or inhibit the ability of integrins to bind to their ligand outside the cell ([Figure 19-65](#)). This regulation is poorly understood, but it may involve the phosphorylation of the cytoplasmic tails of the integrins, the association of the tails with activating cytoplasmic proteins, or both.

The ability of a cell to control integrin-ligand interactions from within is termed *inside-out signaling*. It is particularly important in platelets and white blood cells, where integrins usually have to be activated before they can mediate adhesion. In most other cells, integrins are usually maintained in an

adhesion-competent state. Regulated adhesion allows white blood cells to circulate unimpeded until they are activated by an appropriate stimulus. Because the integrins do not need to be synthesized *de novo*, the signaled adhesion response can be rapid. Platelets, for example, are activated either by contact with a damaged blood vessel or by various soluble signal molecules. In either case, the stimulus triggers intracellular signaling pathways that rapidly activate a β_3 integrin in the platelet membrane. This induces a conformational change in the extracellular domain of the integrin that enables the protein to bind the blood-clotting protein fibrinogen with high affinity. The fibrinogen links platelets together to form a platelet plug, which helps stop bleeding.

Similarly, the weak binding of a T lymphocyte to its specific antigen on the surface of an antigen-presenting cell (discussed in [Chapter 24](#)) triggers intracellular signaling pathways in the T cell that activate its β_2 integrins. The activated integrins then enable the T cell to adhere strongly to the antigen-presenting cell so that it remains in contact long enough to become stimulated fully. The integrins may then return to an inactive state, allowing the T cell to disengage.

There are occasions, especially during development, when cells other than blood cells also regulate the activity of their integrins. If a constitutively active integrin (made by deleting the cytoplasmic tail of the α subunit) is expressed in a developing *Drosophila* embryo, for example, it disrupts normal muscle development. The muscle precursor cells expressing the activated integrin cannot disengage from the extracellular matrix and therefore cannot migrate normally.  [TOP](#)

Integrins Activate Intracellular Signaling Pathways

We have already discussed how integrins function as transmembrane linkers that connect extracellular matrix molecules to actin filaments in the cell cortex and thereby regulate the shape, orientation, and movement of cells. But the clustering of integrins at the sites of contact with the matrix (or with another cell) can also activate intracellular signaling pathways. Signaling is initiated by the assembly of signaling complexes at the cytoplasmic face of the plasma membrane, much as in signaling by conventional signaling receptors (discussed in [Chapter 15](#)).

Whereas activated integrins, like activated conventional signaling receptors, can induce global cell responses, often including changes in gene expression, activated integrins are especially adept at stimulating localized changes in the cytoplasm close to the cell-matrix contact. This may be a fundamental feature of signaling by transmembrane cell adhesion proteins in general. In the developing nervous system, for example, the growing tip of an axon is guided mainly by its responses to local adhesive (and repellent) cues in the environment that are recognized by transmembrane cell adhesion proteins. The

primary effects of the adhesion proteins are thought to result from the activation of intracellular signaling pathways that act locally in the axon tip, rather than through cell-cell adhesion itself or signals conveyed to the cell body.

Many of the signaling functions of integrins depend on a cytoplasmic protein tyrosine kinase called **focal adhesion kinase (FAK)**. Focal adhesions are often the most prominent sites of tyrosine phosphorylation in cells in culture (see [Figure 17-50](#)), and FAK is one of the major tyrosine-phosphorylated proteins found in focal adhesions (although it can also associate with conventional signaling receptors). When integrins cluster at sites of cell-matrix contact, FAK is recruited to focal adhesions by intracellular anchor proteins such as *talin*, which binds to the integrin β subunit, or *paxillin*, which binds to one type of integrin α subunit. The clustered FAK molecules cross-phosphorylate each other on a specific tyrosine, creating a phosphotyrosine docking site for members of the Src family of cytoplasmic tyrosine kinases. These kinases then phosphorylate FAK on additional tyrosines, creating docking sites for a variety of intracellular signaling proteins; they also phosphorylate other proteins at focal adhesions. In this way, the signal is relayed into the cell (as discussed in [Chapter 15](#)).

One way to analyze the function of FAK is to examine focal adhesions in cells from mutant mice that lack the protein. FAK-deficient fibroblasts still adhere to fibronectin and form focal adhesions. Surprisingly, they form too many focal adhesions rather than too few; as a result, cell spreading and migration are slowed ([Figure 19-66](#)). This unexpected finding suggests that FAK normally helps disassemble focal adhesions and that this loss of adhesions is required for normal cell migration. By interacting with both conventional signaling receptors and focal adhesions, FAK can couple migratory signals to changes in cell adhesion. Many cancer cells have elevated levels of FAK, which may help explain why they are often more motile than their normal counterparts.

Integrins and conventional signaling receptors can work together in several ways. The signaling pathways activated by conventional signaling receptors can increase the expression of integrins or extracellular matrix molecules, while those activated by integrins can increase the expression of conventional signaling receptors or the ligands that bind to them. The intracellular signaling pathways themselves can also interact and reinforce one another. While some conventional signaling receptors and integrins activate the Ras/MAP kinase pathway (see [Figure 15-56](#)) independently, for example, they often act together to sustain the activation of this pathway long enough to induce cell proliferation. Integrins and conventional signaling receptors cooperate to stimulate many types of cell response. Many cells in culture, for example, will not grow or proliferate in response to extracellular growth factors unless the cells are attached via integrins to extracellular matrix molecules. For some cell types, including epithelial, endothelial, and muscle cells, even cell survival depends on signaling through integrins. When these cells lose contact with the extracellular matrix, they undergo programmed cell death, or apoptosis. This

dependence on attachment to the extracellular matrix for survival and proliferation may help ensure that the cells survive and proliferate only when they are in their appropriate location, which may protect animals against the spread of cancer cells. Attachment-dependent cell survival is exploited for special purposes in embryonic development, as shown in [Figure 19-67](#). The signaling pathways that integrins activate to promote cell survival are similar to those activated by conventional signaling receptors, as discussed in [Chapters 15](#) and [17](#).

The cell adhesion molecules discussed in this chapter are summarized in [Table 19-7](#).

Summary

Integrins are the principal receptors used by animal cells to bind to the extracellular matrix. They are heterodimers and function as transmembrane linkers between the extracellular matrix and the actin cytoskeleton. A cell can regulate the adhesive activity of its integrins from within. Integrins also function as signal transducers, activating various intracellular signaling pathways when activated by matrix binding. Integrins and conventional signaling receptors often cooperate to promote cell growth, cell survival, and cell proliferation.  [TOP](#)

Figure 19-64. The subunit structure of an integrin cell-surface matrix receptor. Electron micrographs of isolated receptors suggest that the molecule has approximately the shape shown here, with the globular head projecting more than 20 nm from the lipid bilayer. By binding to a matrix protein outside the cell and to the actin cytoskeleton (via the anchor proteins indicated) inside the cell (see Figure 19-12B), the protein serves as a transmembrane linker. The α and β subunits are held together by noncovalent bonds. In the fibronectin receptor shown, the α subunit is made initially as a single 140,000-dalton polypeptide chain, which is then cleaved into one small transmembrane domain and one large extracellular domain that contains four divalent-cation-binding sites; the two domains remain held together by a disulfide bond. The extracellular part of the β subunit contains a single divalent-cation-binding

site, as well as a repeating cysteine-rich region, where intrachain disulfide bonding occurs.

The Plant Cell Wall

The plant cell wall is an elaborate extracellular matrix that encloses each cell in a plant. It was the thick cell walls of cork, visible in a primitive microscope, that in 1663 enabled Robert Hooke to distinguish and name cells for the first time. The walls of neighboring plant cells, cemented together to form the intact plant ([Figure 19-68](#)), are generally thicker, stronger, and, most important of all, more rigid than the extracellular matrix produced by animal cells. In evolving relatively rigid walls, which can be up to many micrometers thick, early plant cells forfeited the ability to crawl about and adopted a sedentary life-style that has persisted in all present-day plants.

The Composition of the Cell Wall Depends on the Cell Type

All cell walls in plants have their origin in dividing cells, as the cell plate forms during cytokinesis to create a new partition wall between the daughter cells (discussed in [Chapter 18](#)). The new cells are usually produced in special regions called *meristems* (discussed in [Chapter 21](#)), and they are generally small in comparison with their final size. To accommodate subsequent cell growth, their walls, called **primary cell walls**, are thin and extensible, although tough. Once growth stops, the wall no longer needs to be extensible: sometimes the primary wall is retained without major modification, but, more commonly, a rigid, **secondary cell wall** is produced by depositing new layers inside the old ones. These may either have a composition similar to that of the primary wall or be markedly different. The most common additional polymer in secondary walls is **lignin**, a complex network of phenolic compounds found in the walls of the xylem vessels and fiber cells of woody tissues. The plant cell wall thus has a "skeletal" role in supporting the structure of the plant as a whole, a protective role as an enclosure for each cell individually, and a transport role, helping to form channels for the movement of fluid in the plant. When plant cells become specialized, they generally adopt a specific shape and produce specially adapted types of walls, according to which the different types of cells in a plant can be recognized and classified ([Figure 19-69](#); see also Panel 21-3).

Although the cell walls of higher plants vary in both composition and

organization, they are all constructed, like animal extracellular matrices, using a structural principle common to all fiber-composites, including fiberglass and reinforced concrete. One component provides tensile strength, while another, in which the first is embedded, provides resistance to compression. While the principle is the same in plants and animals, the chemistry is different. Unlike the animal extracellular matrix, which is rich in protein and other nitrogen-containing polymers, the plant cell wall is made almost entirely of polymers that contain no nitrogen, including *cellulose* and *lignin*. Trees make a huge investment in the cellulose and lignin that comprise the bulk of their biomass. For a sedentary organism that depends on CO₂, H₂O and sunlight, these two abundant biopolymers represent "cheap," carbon-based, structural materials, helping to conserve the scarce fixed nitrogen available in the soil that generally limits plant growth.

In the cell walls of higher plants, the tensile fibers are made from the polysaccharide cellulose, the most abundant organic macromolecule on Earth, tightly linked into a network by *cross-linking glycans*. In primary cell walls, the matrix in which the cellulose network is embedded is composed of *pectin*, a highly hydrated network of polysaccharides rich in galacturonic acid. Secondary cell walls contain additional components, such as lignin, which is hard and occupies the interstices between the other components, making the walls rigid and permanent. All of these molecules are held together by a combination of covalent and noncovalent bonds to form a highly complex structure, whose composition, thickness and architecture depends on the cell type.

We focus here on the primary cell wall and the molecular architecture that underlies its remarkable combination of strength, resilience, and plasticity, as seen in the growing parts of a plant. [↑ TOP](#)

The Tensile Strength of the Cell Wall Allows Plant Cells to Develop Turgor Pressure

The aqueous extracellular environment of a plant cell consists of the fluid contained in the walls that surround the cell. Although the fluid in the plant cell wall contains more solutes than does the water in the plant's external milieu (for example, soil), it is still hypotonic in comparison with the cell interior. This osmotic imbalance causes the cell to develop a large internal hydrostatic pressure, or **turgor pressure**, that pushes outward on the cell wall, just as an inner tube pushes outward on a tire. The turgor pressure increases just to the point where the cell is in osmotic equilibrium, with no net influx of water despite the salt imbalance (see [Panel 11-1](#), pp. 628–629). This pressure is vital to plants because it is the main driving force for cell expansion during growth, and it provides much of the mechanical rigidity of living plant tissues. Compare the wilted leaf of a dehydrated plant, for example, with the turgid leaf of a well-watered one. It is the mechanical strength of the cell wall that allows plant cells to sustain this internal pressure. [↑ TOP](#)

The Primary Cell Wall Is Built from Cellulose Microfibrils Interwoven with a Network of Pectic Polysaccharides

The cellulose molecules provide tensile strength to the primary cell wall. Each molecule consists of a linear chain of at least 500 glucose residues that are covalently linked to one another to form a ribbonlike structure, which is stabilized by hydrogen bonds within the chain (Figure 19-70). In addition, intermolecular hydrogen bonds between adjacent cellulose molecules cause them to adhere strongly to one another in overlapping parallel arrays, forming a bundle of about 40 cellulose chains, all of which have the same polarity. These highly ordered crystalline aggregates, many micrometers long, are called **cellulose microfibrils**, and they have a tensile strength comparable to steel. Sets of microfibrils are arranged in layers, or lamellae, with each microfibril about 20–40 nm from its neighbors and connected to them by long cross-linking glycan molecules that are bound by hydrogen bonds to the surface of the microfibrils. The primary cell wall consists of several such lamellae arranged in a plywoodlike network (Figure 19-71).

The **cross-linking glycans** are a heterogeneous group of branched polysaccharides that bind tightly to the surface of each cellulose microfibril and thereby help to cross-link microfibrils into a complex network. Their function is analogous to that of the fibril-associated collagens discussed earlier (see Figure 19-49). There are many classes of cross-linking glycans, but they all have a long linear backbone composed of one type of sugar (glucose, xylose, or mannose) from which short side chains of other sugars protrude. It is the backbone sugar molecules that form hydrogen bonds with the surface of cellulose microfibrils, cross-linking them in the process. Both the backbone and the side-chain sugars vary according to the plant species and its stage of development.

Coextensive with this network of cellulose microfibrils and cross-linking glycans is another cross-linked polysaccharide network based on pectins (see Figure 19-71). **Pectins** are a heterogeneous group of branched polysaccharides that contain many negatively charged galacturonic acid units. Because of their negative charge, pectins are highly hydrated and associated with a cloud of cations, resembling the glycosaminoglycans of animal cells in the large amount of space they occupy (see Figure 19-37). When Ca^{2+} is added to a solution of pectin molecules, it cross-links them to produce a semirigid gel (it is pectin that is added to fruit juice to make jelly). Certain pectins are particularly abundant in the *middle lamella*, the specialized region that cements together the walls of adjacent cells (see Figure 19-71); here, Ca^{2+} cross-links are thought to help hold cell-wall components together. Although covalent bonds also play a part in linking the components together, very little is known about their nature. Regulated separation of cells at the middle lamella underlies such processes as the ripening of tomatoes and the abscission (detachment) of leaves in the fall.

In addition to the two polysaccharide-based networks that are present in all plant primary cell walls, proteins can contribute up to about 5% of the wall's dry mass. Many of these proteins are enzymes, responsible for wall turnover and remodelling, particularly during growth. Another class of wall proteins contains high levels of hydroxyproline, as in collagen. These proteins are thought to strengthen the wall, and they are produced in greatly increased amounts as a local response to attack by pathogens. From the genome sequence of *Arabidopsis*, it has been estimated that more than 700 genes are required to synthesize, assemble, and remodel the plant cell wall. Some of the main polymers found in the primary and secondary cell wall are listed in [Table 19-8](#).

For a plant cell to grow or change its shape, the cell wall has to stretch or deform. Because of their crystalline structure, however, individual cellulose microfibrils are unable to stretch. Thus, stretching or deformation of the cell wall must involve either the sliding of microfibrils past one another, the separation of adjacent microfibrils, or both. As we discuss next, the direction in which the growing cell enlarges depends in part on the orientation of the cellulose microfibrils in the primary wall, which in turn depends on the orientation of microtubules in the underlying cell cortex at the time the wall was deposited. [↑ TOP](#)

Microtubules Orient Cell-Wall Deposition

The final shape of a growing plant cell, and hence the final form of the plant, is determined by controlled cell expansion. Expansion occurs in response to turgor pressure in a direction that depends in part on the arrangement of the cellulose microfibrils in the wall. Cells, therefore, anticipate their future morphology by controlling the orientation of microfibrils that they deposit in the wall. Unlike most other matrix macromolecules, which are made in the endoplasmic reticulum and Golgi apparatus and are secreted, cellulose, like hyaluronan, is spun out from the surface of the cell by a plasma-membrane-bound enzyme complex (cellulose synthase), which uses as its substrate the sugar nucleotide UDP-glucose supplied from the cytosol. As they are being synthesized, the nascent cellulose chains assemble spontaneously into microfibrils that form on the extracellular surface of the plasma membrane—forming a layer, or lamella, in which all the microfibrils have more or less the same alignment (see [Figure 19-71](#)). Each new lamella forms internally to the previous one, so that the wall consists of concentrically arranged lamellae, with the oldest on the outside. The most recently deposited microfibrils in elongating cells commonly lie perpendicular to the axis of cell elongation ([Figure 19-72](#)). Although the orientation of the microfibrils in the outer lamellae that were laid down earlier may be different, it is the orientation of these inner lamellae that is thought to have a dominant influence on the direction of cell expansion ([Figure 19-73](#)).

An important clue to the mechanism that dictates this orientation came from observations of the microtubules in plant cells. These are arranged in the cortical cytoplasm with the same orientation as the cellulose microfibrils that are currently being deposited in the cell wall in that region. These cortical microtubules form a *cortical array* close to the cytosolic face of the plasma membrane, held there by poorly characterized proteins (Figure 19-74). The congruent orientation of the cortical array of microtubules (lying just inside the plasma membrane) and cellulose microfibrils (lying just outside) is seen in many types and shapes of plant cells and is present during both primary and secondary cell-wall deposition, suggesting a causal relationship.

If the entire system of cortical microtubules is disassembled by treating a plant tissue with a microtubule-depolymerizing drug, the consequences for subsequent cellulose deposition are not as straightforward as might be expected. The drug treatment has no effect on the production of new cellulose microfibrils, and in some cases cells can continue to deposit new microfibrils in the preexisting orientation. Any developmental change in the microfibril pattern that would normally occur between successive lamellae, however, is invariably blocked. It seems that a preexisting orientation of microfibrils can be propagated even in the absence of microtubules, but any change in the deposition of cellulose microfibrils requires that intact microtubules be present to determine the new orientation.

These observations are consistent with the following model. The cellulose-synthesizing complexes embedded in the plasma membrane are thought to spin out long cellulose molecules. As the synthesis of cellulose molecules and their self-assembly into microfibrils proceeds, the distal end of each microfibril presumably forms indirect cross-links to the previous layer of wall material as it becomes integrated into the texture of the wall. At the growing, proximal end of each microfibril, the synthesizing complexes would therefore need to move through the membrane in the direction of synthesis. Since the growing cellulose microfibrils are stiff, each layer of microfibrils would tend to be spun out from the membrane in the same orientation as the previously laid down layer, with the cellulose synthase complex following along the preexisting tracks of oriented microfibrils outside the cell. Oriented microtubules inside the cell, however, can change this predetermined direction in which the synthase complexes move: they can create boundaries in the plasma membrane that act like the banks of a canal to constrain movement of the synthase complexes (Figure 19-75). In this view, cellulose synthesis can occur independently of microtubules but is constrained spatially when cortical microtubules are present to define membrane domains within which the enzyme complex can move.

Plant cells can change their direction of expansion by a sudden change in the orientation of their cortical array of microtubules. Because plant cells cannot move (being constrained by their walls), the entire morphology of a multicellular plant depends on the coordinated, highly patterned control of cortical microtubule orientations during plant development. It is not known

how the organization of these microtubules is controlled, although it has been shown that they can reorient rapidly in response to extracellular stimuli, including low-molecular-weight plant growth regulators such as ethylene and gibberellic acid (see [Figure 21-113](#)). [↑ TOP](#)

Summary

Plant cells are surrounded by a tough extracellular matrix in the form of a cell wall, which is responsible for many of the unique features of a plant's life style. The cell wall is composed of a network of cellulose microfibrils and cross-linking glycans embedded in a highly cross-linked matrix of pectin polysaccharides. In secondary cell walls, lignin may be deposited. A cortical array of microtubules can determine the orientation of newly deposited cellulose microfibrils, which in turn determines directional cell expansion and therefore the final shape of the cell and, ultimately, of the plant as a whole. Figure 19-72. The orientation of cellulose microfibrils in the primary cell wall of an elongating carrot cell. This electron micrograph of a shadowed replica from a rapidly frozen and deep-etched cell wall shows the largely parallel arrangements of cellulose microfibrils, oriented perpendicular to the axis of cell elongation. The microfibrils are cross-linked by, and interwoven with, a complex web of matrix molecules (compare with [Figure 19-71](#)). (Courtesy of Brian Wells and Keith Roberts.)

Figure 19-73. How the orientation of cellulose microfibrils within the cell wall influences the direction in which the cell elongates. The cells in (A) and (B) start off with identical shapes (shown here as cubes) but with different orientations of cellulose microfibrils in their walls. Although turgor pressure is uniform in all directions, cell-wall weakening causes each cell to elongate in a direction perpendicular to the orientation of the microfibrils, which have great tensile strength. The final shape of an organ, such as a shoot, is determined by the direction in which its cells expand.

Figure 19-75. One model of how the orientation of newly deposited cellulose microfibrils might be determined by the orientation of cortical microtubules. The large cellulose synthase complexes are integral membrane proteins that continuously synthesize cellulose microfibrils on the outer face of the plasma membrane. The distal ends of the stiff microfibrils become integrated into the texture of the wall, and their elongation at the proximal end pushes the synthase complex along in the plane of the membrane. Because the cortical array of microtubules is attached to the plasma membrane in a way that confines this complex to defined membrane channels, the orientation of these microtubules—when they are present—determines the axis along which the new microfibrils are laid down.

20. Germ Cells and Fertilization

Sex is not absolutely necessary. Single-celled organisms can reproduce by simple mitotic division, and many plants propagate vegetatively, by forming multicellular offshoots that later detach from the parent. Likewise, in the animal kingdom, a solitary multicellular *Hydra* can produce offspring by budding ([Figure 20-1](#)). Sea anemones and marine worms can split into two half-organisms, each of which then regenerates its missing half. There are even species of lizards that consist only of females and reproduce without mating. Although such asexual reproduction is simple and direct, it gives rise to offspring that are genetically identical to the parent organism. In sexual reproduction, on the other hand, the genomes from two individuals are mixed to produce offspring that differ genetically from one another and from both their parents. This mode of reproduction apparently has great advantages, as the vast majority of plants and animals have adopted it. Even many procaryotes and other organisms that normally reproduce asexually engage in occasional bouts of sexual reproduction, thereby creating offspring with new combinations of genes. This chapter describes the cellular machinery of sexual reproduction. Before discussing in detail how the machinery works, however, we shall pause briefly to consider why it exists and what benefits it brings. [↑ TOP](#)

Molecular Biology of the Cell → V. Cells in Their Social Context → 20. Germ Cells and Fertilization

Human fertilization in vitro. Four sequential stages of fertilization are shown, beginning with a mature, but unfertilized human egg (*top left*). Next comes the post-fertilization incorporation of a sperm pronucleus, which in this example is moving inward from the left (*top right*). This stage is followed by the fusion of the egg and sperm pronuclei (*bottom left*), which in turn leads to the alignment of the mixed chromosomes from both parents on the first mitotic spindle (*bottom right*). The Benefits of Sex

In the sexual reproductive cycle, haploid generations of cells, each carrying a single set of chromosomes, alternate with diploid generations of cells, each carrying a double set of chromosomes (Figure 20-2). Genomes mix when two haploid cells fuse to form a diploid cell. Later, new haploid cells are generated when a descendant of this diploid cell divides by the process of *meiosis*. During meiosis, the chromosomes of the double chromosome set exchange DNA by *genetic recombination* before being shared out, in new combinations, into single chromosome sets. Because each single chromosome set will contain genes originating from one ancestral cell of the previous haploid generation mixed with genes from the other ancestral cell, each cell of the new haploid generation will receive a novel assortment of genes. Thus, through cycles of haploidy, cell fusion, diploidy, and meiosis, old combinations of genes are broken up and new combinations are created.

In Multicellular Animals and Most Plants, the Diploid Phase Is Complex and Long, the Haploid Simple and Fleeting

Cells proliferate by mitotic division. In most organisms that reproduce sexually, this proliferation occurs during the diploid phase. Some primitive organisms, such as fission yeasts, are exceptional in that the haploid cells proliferate mitotically and the diploid cells, once formed, proceed directly to meiosis. A less extreme exception occurs in plants, where mitotic cell divisions occur in both the haploid and the diploid phases. In all but the most primitive plants, such as mosses and ferns, however, the haploid phase is very brief and simple, while the diploid phase is extended into a long period of development and proliferation. For almost all multicellular animals, including vertebrates, practically the whole of the life cycle is spent in the diploid state: the haploid cells exist only briefly, do not divide at all, and are highly specialized for sexual fusion (Figure 20-3).

Haploid cells that are specialized for sexual fusion are called gametes. Typically, two types of gametes are formed: one is large and nonmotile and is referred to as the *egg* (or *ovum*); the other is small and motile and is referred to

as the *sperm* (or *spermatozoon*) (Figure 20-4). During the diploid phase that follows the fusion of gametes, the cells proliferate and diversify to form a complex multicellular organism. In most animals, a useful distinction can be drawn between the cells of the germ line, from which the next generation of gametes will be derived, and the somatic cells, which form the rest of the body and ultimately leave no progeny. In a sense, the somatic cells exist only to help the cells of the germ line (the germ cells) survive and propagate. [↑ TOP](#)

Sexual Reproduction Gives a Competitive Advantage to Organisms in an Unpredictably Variable Environment

The machinery of sexual reproduction is elaborate, and the resources spent on it are large (Figure 20-5). What benefits does it bring, and why did it evolve? Through genetic recombination, sexual individuals produce unpredictably dissimilar offspring, whose haphazard genotypes are at least as likely to represent a change for the worse as a change for the better. Why, then, should sexual individuals have a competitive advantage over individuals that breed true, by an asexual process? This problem continues to perplex population geneticists, but the general conclusion seems to be that the reshuffling of genes in sexual reproduction helps a species to survive in an unpredictably variable environment. If a parent produces many offspring with a wide variety of gene combinations, there is a better chance that at least one of the offspring will have the assortment of features necessary for survival. Sexual reproduction also allows the many deleterious mutations that accumulate randomly to be eliminated, while permitting the rare advantageous mutations that arise in separate individuals to be combined in a single individual.

Whatever the benefits of sex may be, it is striking that practically all complex present-day organisms have evolved largely through generations of sexual, rather than asexual, reproduction. Asexual organisms, although plentiful, seem mostly to have remained simple and primitive.

We now turn to the cellular mechanisms of sex, beginning with the events of meiosis, which segregates the chromosomes into new sets, as the diploid cells in the germ line divide to produce haploid gametes. We then focus our discussion on mammals. We consider the diploid cells of the germ line that give rise to the gametes and how the sex of a mammal is determined. Finally, we discuss the nature of the gametes themselves, as well as the process of *fertilization*, in which two gametes fuse to form a *zygote*, which develops into a new diploid organism. [↑ TOP](#)

Summary

Sexual reproduction has been favored by evolution probably because the random recombination of genetic information improves the chances of producing at least some offspring that will survive in an unpredictably variable

environment. The sexual reproductive cycle involves an alternation of diploid and haploid states: diploid cells divide by meiosis to form haploid cells, and the haploid cells from two individuals fuse in pairs at fertilization to form new diploid cells. In the process, genomes are mixed and recombined to produce individuals that inherit novel assortments of genes. Most of the life cycle of higher plants and animals is spent in the diploid phase; only a small proportion of the diploid cells (those in the germ line) undergo meiosis to produce haploid cells (the gametes), and the haploid phase is very brief. Figure 20-3. Haploid and diploid cells in the life cycle of higher and some lower eucaryotes. The haploid cells are shown in *red* and the diploid cells in *blue*. Cells in higher eucaryotic organisms usually proliferate in the diploid phase to form a multicellular organism; only the gametes are haploid, and they fuse at fertilization to form a diploid zygote, which develops into a new individual. In some lower eucaryotes, by contrast, the haploid cells proliferate, and the only diploid cell is the zygote, which exists transiently after mating.

Meiosis

The realization that gametes are haploid, and must therefore be produced by a special type of cell division, came from an observation that was also among the first to suggest that chromosomes carry genetic information. In 1883, it was discovered that, whereas the fertilized egg of a roundworm contains four chromosomes, the nucleus of the egg and that of the sperm each contain only two chromosomes. The chromosome theory of heredity therefore explained the long-standing paradox that the maternal and paternal contributions to the character of the progeny seem to be equal, despite the enormous difference in size between the egg and sperm (see [Figure 20-4](#)).

The finding also implied that germ cells must be formed by a special kind of nuclear division in which the chromosome complement is precisely halved. This type of division is called meiosis, from the Greek, meaning diminution. (*Mitosis*, which refers to the nuclear division that occurs during an ordinary mitotic cell division (discussed in [Chapter 18](#)), is from the Greek word *mitos*, meaning "a thread." The term refers to the threadlike appearance of the chromosomes as they condense during nuclear division—a process that occurs in both meiotic and mitotic divisions.) The behavior of the chromosomes during meiosis turned out to be considerably more complex than expected. Consequently, it was not until the early 1930s, as a result of painstaking cytological and genetic studies, that the essential events of meiosis were finally established. More recent genetic and molecular studies have begun to identify the meiosis-specific proteins that cause the chromosomes to behave in a special way and mediate the genetic recombination events that occur in meiosis.

Duplicated Homologous Chromosomes Pair During Meiosis

The set of chromosomes of a typical sexually-reproducing organism consists of *autosomes*, which are common to all members of the species, and *sex chromosomes*, which are differently allocated according to the sex of the individual. A diploid nucleus contains two closely similar versions of each chromosome. For each of the autosomal chromosome pairs, one member was initially inherited from the male parent (a paternal chromosome) and the other

was initially inherited from the female parent (a maternal chromosome). The two versions, which are very similar but not identical in DNA sequence, are called homologs, and in most cells they maintain a completely separate existence as independent chromosomes.

After a chromosome is duplicated by DNA replication, the twin copies of the fully replicated chromosome at first remain tightly linked along their length and are called **sister chromatids**. In a mitotic cell division, the sister chromatids line up at the equator of the spindle with their *kinetochores* (protein complexes associated with the centromeres, discussed in [Chapter 18](#)) and attached microtubules pointing toward opposite poles. The sister chromatids then separate completely from each other at anaphase to become individual chromosomes. In this manner each daughter cell formed by a mitotic cell division inherits one copy of each paternal chromosome and one copy of each maternal chromosome and is therefore unchanged in its genetic composition from the parent cell.

In contrast, a haploid gamete produced from a diploid cell through meiosis must contain half the original number of chromosomes. It must contain only one chromosome in place of each homologous pair of chromosomes, so it is endowed with either the maternal or the paternal copy of each gene but not both. This requirement makes an extra demand on the machinery for cell division. The mechanism that has evolved to accomplish the additional sorting requires that homologs recognize each other and become physically connected side-by-side along their entire length before they line up on the spindle. How the maternal and the paternal copy of each chromosome recognize each other is still uncertain. In many organisms, the initial association (a process called **pairing**) seems to be mediated by complementary DNA base-pair interactions at numerous and widely dispersed sites along the chromosomes.

Before the homologs pair, each chromosome in the diploid cell replicates to produce two sister chromatids, just as in a mitotic cell division. It is only after DNA replication has been completed that the special features of meiosis become evident. Each duplicated chromosome pairs with its duplicated homolog, forming a structure called a bivalent, which contains four chromatids. The pairing occurs during a long meiotic prophase, which often lasts for days and can last for years. As we shall see, pairing allows genetic recombination to occur, whereby a fragment of a maternal chromatid may be exchanged for a corresponding fragment of a homologous paternal chromatid. At the subsequent metaphase all of the bivalents line up on the spindle, and at anaphase the two duplicated homologs (each consisting of two sister chromatids) separate from each other and move to opposite poles of the spindle, and the cell divides ([Figure 20-6](#)). To produce haploid gametes, however, another cell division is required. [↑ TOP](#)

Gametes Are Produced by Two Meiotic Cell Divisions

Search

This book
books

All

PubMed

The meiotic cell division just described—referred to as division I of meiosis—does not produce cells with a haploid amount of DNA. Because the sister chromatids behave as a unit, each daughter cell of this division inherits two copies of one of the two homologs. The two copies are identical except where genetic recombination has occurred. The two daughter cells therefore contain a haploid number of chromosomes but a diploid amount of DNA. They differ from normal diploid cells in two ways. First, the two DNA copies of each chromosome derive from only one of the two homologous chromosomes in the original cell (except for the bits exchanged by genetic recombination). Second, these two DNA copies are inherited as joined sister chromatids (see Figure 20-6).

Formation of the actual gamete nuclei can now proceed simply through a second cell division, division II of meiosis, without further DNA replication. The duplicated chromosomes align on a second spindle, and the sister chromatids separate to produce cells with a haploid DNA content. Meiosis thus consists of a single phase of DNA replication followed by two cell divisions. Four haploid cells are therefore produced from each cell that enters meiosis. Meiosis and mitosis are compared in Figure 20-7.

Occasionally during meiosis, chromosomes fail to separate normally into the four haploid cells, a phenomenon known as *nondisjunction*. In such abnormal meiotic divisions some of the haploid cells that are produced lack a chromosome, while others have more than one copy. The resulting gametes form abnormal embryos, most of which die. Some survive, however: *Down syndrome* in humans, for example, is caused by an extra copy of chromosome 21, resulting from nondisjunction during meiotic division I or II. The vast majority of such segregation errors occur during meiosis in females, and the error rate increases with advancing maternal age. The frequency of missegregation in human oocytes is remarkably high (about 10% of meioses), and this is thought to be one reason for the high rate of miscarriages (spontaneous abortions) in early pregnancy. [↑ TOP](#)

Genetic Reassortment Is Enhanced by Crossing-over Between Homologous Nonsister Chromatids

Unless they are identical twins, which develop from a single zygote, no two offspring of the same parents are genetically the same. This is because, long before the two gametes fuse at fertilization, two kinds of randomizing genetic reassortment have occurred during meiosis.

One kind of reassortment is a consequence of the random distribution of the maternal and paternal homologs between the daughter cells at meiotic division I, as a result of which each gamete acquires a different mixture of maternal and paternal chromosomes. From this process alone, one individual could, in principle, produce 2^n genetically different gametes, where n is the haploid

number of chromosomes ([Figure 20-8A](#)). In humans, for example, each individual can produce at least $2^{23} = 8.4 \times 10^6$ genetically different gametes. But the actual number of variants is very much greater than this because a second type of reassortment, called chromosomal crossing-over, occurs during meiosis. It takes place during the long prophase of meiotic division I (prophase I), in which parts of homologous chromosomes are exchanged. On average, between two and three crossover events occur on each pair of human chromosomes during meiotic division I. This process scrambles the genetic constitution of each of the chromosomes in gametes, as illustrated in [Figure 20-8B](#).

During chromosomal crossing-over, the DNA double helix is broken in both a maternal chromatid and a homologous paternal chromatid, so as to exchange fragments between the two nonsister chromatids in a reciprocal fashion by a process known as **genetic recombination**. The molecular details of this process are discussed in [Chapter 5](#). The consequences of each crossover event can be observed in the microscope at the latest stages of prophase I, when the chromosomes in the bivalents are highly condensed. At this stage, the sister chromatids are tightly apposed along their entire length, and the two duplicated homologs (maternal and paternal) that form each bivalent are seen to be physically connected at specific points. Each connection, called a chiasma (plural **chiasmata**), corresponds to a crossover between two nonsister chromatids ([Figure 20-9](#)). Each of the two chromatids of a duplicated chromosome can cross over with either of the two chromatids of the other chromosome in the bivalent, as illustrated in [Figure 20-10](#).

At this stage of meiosis, each pair of duplicated homologs is held together by at least one chiasma. Many bivalents contain more than one chiasma, indicating that multiple crossovers can occur between homologs. [↑ TOP](#)

Chiasmata Have an Important Role in Chromosome Segregation in Meiosis

In addition to reassorting genes, chromosomal crossing-over is crucial in most organisms for the correct segregation of the two duplicated homologs to separate daughter nuclei. This is because the chiasmata created by crossover events have a crucial role in holding the maternal and paternal homologs together until the spindle separates them at anaphase I (see [Figure 20-9](#)). Before anaphase I, the two poles of the spindle pull on the duplicated homologs in opposite directions, and the chiasmata resist this pulling. In mutant organisms that have a reduced frequency of meiotic chromosome crossing-over, some of the chromosome pairs lack chiasmata. These pairs fail to segregate normally, and many of the resulting gametes contain too many or too few chromosomes.

The duplicated homologs are held together at chiasmata only because the arms

of sister chromatids are glued together along their length by proteins called *cohesins* (discussed in [Chapter 18](#); see [Figure 20-9](#)). In *Drosophila*, for example, if a meiosis-specific cohesin is defective, sister chromatids separate prior to metaphase I and, as a consequence, the homologs segregate abnormally.

As illustrated in [Figure 20-11](#), the arms of sister chromatids suddenly become unglued at the start of anaphase I, when the cohesins holding the arms together are degraded, allowing the duplicated homologs to separate and be pulled to opposite poles of the spindle. The sister chromatids of each duplicated homolog remain attached at the centromere by meiosis-specific cohesins, which are degraded at anaphase of meiotic division II (anaphase II); only then can the sister chromatids separate.

In meiotic division II, as in a mitotic division, the kinetochores on each sister chromatid have attached kinetochore microtubules pointing in opposite directions, so that the chromatids are drawn into different daughter cells at anaphase. In meiotic division I, by contrast, the kinetochores on both sister chromatids behave as a single functional unit, as their attached kinetochore microtubules all point in the same direction so that the sister chromatids stay together when the duplicated homologs separate (see [Figure 20-11](#)). In budding yeasts, a meiosis-specific protein located at the kinetochores of meiosis I chromosomes has been shown to be required for this special behavior. [↑ TOP](#)

Pairing of the Sex Chromosomes Ensures That They Also Segregate

We have seen that duplicated homologous chromosomes must pair and form at least one chiasma during the first meiotic division if they are to segregate accurately between the daughter cells. But what happens to the sex chromosomes? Female mammals have two X chromosomes, which can pair and segregate like other homologs. But males have one X and one Y chromosome, and these chromosomes are not homologous. Yet, they must pair and then cross over during the first metaphase of meiosis if the sperm are to contain either one Y or one X chromosome and not both or neither. The crossovers are possible because of a small region of homology between the X and the Y at one end of these chromosomes. The two chromosomes pair and cross over in this region during prophase I. The chiasmata resulting from this genetic recombination keep the X and Y chromosomes connected on the spindle so that only two types of sperm are normally produced: sperm containing one Y chromosome, which will give rise to male embryos, and sperm containing one X chromosome, which will give rise to female embryos.

Having considered the general way in which chromosomes behave and segregate during meiosis, we now return to the process of genetic recombination that occurs during the long prophase of meiotic division I and

has such an important role in reassorting genes during gamete formation. [↑ TOP](#)

Meiotic Chromosome Pairing Culminates in the Formation of the Synaptonemal Complex

A series of complex events occurs during the long prophase of meiotic division I: duplicated homologous chromosomes pair, genetic recombination is initiated between nonsister chromatids, and each pair of duplicated homologs assembles into an elaborate structure called the synaptonemal complex. In some organisms, genetic recombination begins before the synaptonemal complex assembles and is required for the complex to form; in others, the complex can form in the absence of recombination. In all organisms, however, the recombination process is completed while the DNA is held in the synaptonemal complex, which serves to space out the crossover events along each chromosome.

The prophase of meiotic division I is traditionally divided into five sequential stages—*leptotene*, *zygotene*, *pachytene*, *diplotene*, and *diakinesis*—defined by the morphological changes associated with the assembly (*synapsis*) and disassembly (*desynapsis*) of the synaptonemal complex. Prophase begins with leptotene, when the duplicated paired homologs condense. At zygotene, the synaptonemal complex begins to develop between the two sets of sister chromatids in each bivalent. Pachytene begins when synapsis is complete, and it generally persists for days, until desynapsis begins the diplotene stage, in which the chiasmata are first seen ([Figure 20-12](#)).

The synaptonemal complex consists of a long, ladderlike protein core, on opposite sides of which the two duplicated homologs are aligned to form a long linear chromosome pair ([Figure 20-13](#)). The sister chromatids in each homolog are kept tightly packed together, with their DNA extending from their own side of the protein ladder in a series of loops. In the central region, a central element is connected by transverse filaments to lateral elements that run along each pair of sister chromatids, forming the sides of the ladder.

Several protein components of the synaptonemal complex have been identified and localized to specific structures of the complex. Yeast mutants that lack specific components have provided insights into the functions of the complex and some of its proteins. One yeast protein, for example, seems to nucleate the assembly of the lateral elements: if this protein is defective, these elements fail to form. Another yeast protein helps to form the transverse filaments: if this protein is absent, homolog pairing occurs without intimate synapsis, while an abnormally long mutant form of the protein creates a larger than normal separation between the two lateral elements of the synaptonemal complex. [↑ TOP](#)

Recombination Nodules Mark the Sites of Genetic Recombination

The crossover events that take place during the prophase of meiotic division I can occur nearly anywhere along a chromosome. They are not distributed uniformly, however: there are recombination "hot spots," where double-stranded DNA breaks seem to be preferentially induced by the meiotic endonuclease called *Spo11*. Moreover, both genetic and cytological experiments indicate that the occurrence of one crossover event decreases the probability of a second occurring at a nearby chromosomal site. This "interference" seems to ensure that the limited number of crossovers are spread out so that even small chromosomes get at least one, as required for the homologs to segregate normally. Although the molecular basis of the interference is unknown, the synaptonemal complex is thought to mediate the process.

There is strong indirect evidence that the general genetic recombination events in meiosis are catalyzed by **recombination nodules**. These are very large protein complexes that sit at intervals on the synaptonemal complex, placed like basketballs on a ladder between the two homologous chromosomes (see [Figure 20-13](#)). These nodules contain Rad51, which is the eucaryotic version of the RecA protein, which mediates general recombination in *E. coli* (discussed in [Chapter 5](#)). They seem to mark the site of a multienzyme "recombination machine" that interacts with local regions of DNA on the maternal and paternal chromatids across the 100-nm-wide synaptonemal complex.

There are two main types of recombination nodule. *Early nodules* are present before pachytene and are thought to mark the sites of the initial DNA-strand-exchange events of the recombination process. *Late nodules* are less numerous, are present during pachytene, and are thought to mark the sites where the initial strand-exchange events are being resolved as stable crossovers. Proteins known to be involved in general recombination have been identified in recombination nodules, and there is a strong correspondence between the number and distribution of late nodules and the number and distribution of crossovers. Moreover, meiosis-specific versions of proteins involved in mismatch DNA repair (discussed in [Chapter 5](#)) are also located in late nodules, where they help to resolve recombination intermediates as stable crossovers.

The occurrence of crossovers has enabled geneticists to map the relative positions of genes on chromosomes, as we now explain. Such maps have been crucial in the cloning of human disease genes. [↑ TOP](#)

Genetic Maps Reveal Favored Sites for Crossovers

On average, a human chromosome participates in two or three crossover events during meiosis, and every chromosome participates in at least one.

Thus, whereas two genes very close to each other on a chromosome almost always end up together in the same gamete after meiosis, two genes located at the opposite ends of a chromosome are no more likely to end up together than are genes located on different chromosomes. One can therefore determine whether two genes—a gene with a mutant form causing congenital deafness, for example, and a second gene with a mutant form causing muscular dystrophy—are located close together on the same chromosome. This is done by measuring the frequency with which a child inherits the mutant forms of both genes from a parent that carries one mutant and one nonmutant version of each of them. If the two mutant genes are on different chromosomes, one will be inherited without the other 50% of the time, as chromosomes are independently segregated at meiosis. The same result is expected, however, if the two mutant genes are far apart on the same chromosome, as one or more crossover events will separate them at meiosis. To determine whether genes are on the same chromosome and, if so, how close they are to one another, human geneticists measure the frequency of coinheritance of many genes in large numbers of families. In this way, they can discover not only the neighbors of a particular gene but also the neighbors of the neighbors and thereby work their way down an entire chromosome. By this means, they have defined 24 *linkage groups*, one corresponding to each human chromosome (22 autosome pairs plus 2 sex chromosomes).

Using such measurements, geneticists have constructed detailed genetic maps of the entire human genome, in which the distance between each pair of neighboring genes is displayed as the percentage recombination between them. The standard unit of genetic distance is the *centimorgan (cM)*, which corresponds to a 1% probability that two genes will be separated by a crossover event during meiosis. A typical human chromosome is more than 100 centimorgans long, indicating that more than one crossover is likely to occur on a typical human chromosome.

Another way to construct a genetic map is to measure the coinheritance of short DNA sequences (called *DNA markers*) that differ between individuals in the population—that is, that are *polymorphic* (see p. 464). Genetic maps constructed in this way have two advantages over genetic maps constructed by tracing the phenotypes of individuals that inherit mutant genes. First, they can be more detailed, as there are large numbers of DNA markers that can be measured. Second, they can reveal the real distance in nucleotide pairs between the markers, so that genetic distances in centimorgans can be compared directly with true physical distances along a chromosome.

A direct comparison of genetic and physical distances on part of a budding yeast chromosome is shown in Figure 20-14. As the entire DNA sequence of this organism's genome is known, the physical map indicates the true distances between the DNA markers. The regions of the genetic map that are expanded in comparison with the physical map indicate recombination "hotspots," where crossovers during meiosis occur with an unusually high frequency. Regions that are contracted indicate recombination "coldspots," where crossovers occur

with unusually low frequency. Human genetic maps show similar expansions and contractions. A likely explanation for the hotspots is that they contain an abundance of sites where the DNA helix is cut by the meiotic endonuclease (Spo11) that creates the double-strand DNA breaks that begin the recombination process (see [Figure 5-56](#)). [↑ TOP](#)

Meiosis Ends with Two Successive Cell Divisions Without DNA Replication

Prophase I can occupy 90% or more of the time taken by meiosis. Although it is traditionally called prophase, it actually resembles the G₂ phase of a mitotic cell division. The nuclear envelope remains intact and disappears only when the meiotic spindle begins to form, as prophase I gives way to metaphase I. After prophase I is completed, two successive cell divisions follow without an intervening period of DNA synthesis. These divisions produce four cells from one and bring meiosis to an end (see [Figure 20-7](#)).

Meiotic division I is far more complex and requires much more time than either mitosis or meiotic division II. Even the preparatory DNA replication during meiotic division I tends to take much longer than an ordinary S phase, and cells can then spend days, months, or even years in prophase I, depending on the species and on the gamete being formed ([Figure 20-15](#)).

When meiotic division I ends, nuclear membranes re-form around the two daughter nuclei, and the brief interphase of division II begins. During this period, the chromosomes may decondense somewhat, but usually they soon recondense and prophase II begins. (Because there is no DNA synthesis during this interval, in some organisms the chromosomes seem to pass almost directly from one division phase into the next.) Prophase II is brief: the nuclear envelope breaks down as the new spindle forms, after which metaphase II, anaphase II, and telophase II usually follow in quick succession. After nuclear envelopes have formed around the four haploid nuclei produced at telophase II, cytokinesis occurs, and meiosis is complete (see [Figure 20-7](#)).

As in mitosis, a separate set of kinetochore microtubules is present on each sister chromatid at metaphase II, and these two sets of microtubules extend in opposite directions (see [Figure 20-11](#)). In mitosis, however, the sister chromatids are glued together along their length, as well as at the centromere, and both types of contact are released at the start of anaphase. In meiosis, by contrast, the sister chromatids come apart in two steps—their arms have separated at anaphase I, while their centromeres remain attached, separating only at anaphase II (see [Figures 20-7](#) and [20-11](#)).

The principles of meiosis are the same in plants and animals and in males and females. But the production of gametes involves more than just meiosis, and the other processes required vary widely among organisms and are very

different for eggs and sperm. We shall focus our discussion of gametogenesis mainly on mammals. As we shall see, by the end of meiosis a mammalian egg is fully mature, whereas a sperm that has completed meiosis has only just begun its differentiation. Before discussing these gametes, however, we consider how certain cells in the mammalian embryo become committed to developing into germ cells and how these cells then become committed to developing into either sperm or eggs, depending on the sex of the individual. [↑ TOP](#)

Summary

The formation of both eggs and sperm begins in a similar way, with meiosis. In this process two successive cell divisions following one round of DNA replication give rise to four haploid cells from a single diploid cell. Meiosis is dominated by prophase of meiotic division I, which can occupy 90% or more of the total meiotic period. As it enters this prophase, each chromosome consists of two tightly joined sister chromatids. The two replicated homologs present in each diploid nucleus then pair to form a bivalent, consisting of four chromatids. Chromosomal crossover events occur during this time. Each results in the formation of a chiasma, which helps hold each pair of homologs together during metaphase I. Crossing-over has an important role in reassorting genes during gamete formation, and it allows geneticists to map the relative positions of genes on chromosomes. The pairing of homologs culminates in the formation of a synaptonemal complex, which somehow serves to spread out the crossover events along the chromosomes. At anaphase of the first meiotic cell division, the arms of the sister chromatids suddenly become unglued, causing one member of each chromosome pair, still composed of a pair of sister chromatids linked at their centromeres, to be distributed to each daughter nucleus. A second cell division cycle, without DNA replication, then rapidly ensues; in anaphase II, each sister chromatid separates from its sister and is segregated into a separate haploid nucleus. Figure 20-12. Chromosome synapsis and desynapsis during the different stages of meiotic prophase I. (A) A single bivalent is shown. The pachytene stage is defined as the period during which a fully formed synaptonemal complex exists. At leptotene, the two sister chromatids condense, and their chromatin loops each extend from a common protein axis (red). As meiosis progresses, the two homologs become tightly connected by proteins that form the central region of the synaptonemal complex, composed of a central element (blue), transverse filaments (thin black lines), and the lateral elements (red) that anchor the chromatin loops. In the gametes of many female animals, but not those of mammals, the subsequent diplotene stage is an enormously prolonged period of cell growth, during which the chromosomes are decondensed and very active in transcription. Diplotene ends with diakinesis—the stage of transition to metaphase—in which the chromosomes recondense and transcription halts. In male gametes, diplotene and diakinesis are briefer and less distinct. (B) An electron micrograph of a synaptonemal complex from a meiotic cell at pachytene in a lily flower. Primordial Germ Cells and Sex Determination in Mammals

Sexual reproductive strategies can vary enormously between different organisms. In the rest of this chapter, we focus mainly on the strategies used by mammals.

In all vertebrate embryos, certain cells are singled out early in development as progenitors of the gametes. These primordial germ cells migrate to the developing gonads, which will form the *ovaries* in females and the *testes* in males. After a period of mitotic proliferation, the primordial germ cells undergo meiosis and differentiate into mature gametes—either eggs or sperm. Later, the fusion of egg and sperm after mating initiates embryogenesis. The subsequent production in this embryo of new primordial germ cells begins the cycle again.

In this section, we consider how mammalian primordial germ cells arise, how the sex of a mammal is determined, and how sex determination dictates whether the primordial germ cells develop into sperm or eggs.

Primordial Germ Cells Migrate into the Developing Gonad

In most animals, including many vertebrates, the unfertilized egg is asymmetrical, with different regions of cytoplasm containing different sets of mRNA and protein molecules (discussed in Chapter 21). When the egg is fertilized and divides repeatedly to produce the cells of the early embryo, the cells that inherit specific molecules localized in a particular region of the egg cytoplasm become primordial germ cells. In mammals, by contrast, the egg is more symmetrical, and the cells produced by the first few divisions of the fertilized egg are all *totipotent*—that is, they can give rise to any of the cell types in the body, including germ cells. A small group of cells in the early mammalian embryo is induced to become primordial germ cells by signals produced by neighboring cells. In mice, for example, 1 week after fertilization, about 50 cells in tissue lying outside the embryo proper are induced by their neighbors to become primordial germ cells. In the next few days, these cells proliferate and are swept back into the embryo proper along with the

invaginating hindgut. They then actively migrate through the gut to their final destination in the developing gonads ([Figure 20-16](#)). As the primordial germ cells migrate through the embryo, they are signaled to survive, proliferate, and migrate by various extracellular proteins produced by adjacent somatic cells.

After the primordial germ cells enter the developing mouse gonad, which at this stage is called the *genital ridge*, they continue to proliferate for 2 or 3 more days. At this point, they commit to a developmental pathway that will lead them to become either eggs or sperm, depending not on their own sex chromosome constitution but on whether the genital ridge has begun to develop into an ovary or a testis, respectively. The sex chromosomes in the somatic cells of the genital ridge determine which type of gonad the ridge becomes. A single gene on the Y chromosome has an especially important role in this decision. [↑ TOP](#)

The Sry Gene on the Y Chromosome Can Redirect a Female Embryo to Become a Male

Aristotle believed that the temperature of the male during sexual intercourse determined the sex of offspring: the higher the temperature, the greater the chance of producing a male. We now know that the sex of a mammal is determined by its sex chromosomes, rather than by the environment (although for some animals, such as crocodiles and many fish, the opposite is true). Female mammals have two X chromosomes in all of their somatic cells, whereas males have one X and one Y. The Y chromosome is the determining factor. Individuals with a Y chromosome develop as males no matter how many X chromosomes they have, whereas individuals without a Y chromosome develop as females, even if they have only one X chromosome. The sperm that fertilizes the egg determines the sex of the resulting zygote: eggs have a single X chromosome, whereas the sperm can have either an X or a Y.

The Y chromosome influences the sex of the individual by inducing the somatic cells of the genital ridge to develop into a testis instead of an ovary. The crucial gene on the Y chromosome that has this *testis determining* function is called **Sry**, for "sex-determining region of Y." Remarkably, when this gene is introduced into the genome of an XX mouse zygote, the transgenic embryo produced develops as a male, even though it lacks all of the other genes on the Y chromosome ([Figure 20-17](#)). Such mice, however, cannot produce sperm, in part, at least, because the presence of two X chromosomes suppresses sperm development.

Sry is expressed only in a subset of the somatic cells of the developing gonad, and it causes these cells to differentiate into **Sertoli cells**, which are the main type of supporting cells found in the testis. The Sertoli cells direct sexual development along a male pathway by affecting other cells in the genital ridge in at least four ways:

1. They stimulate the newly arriving primordial germ cells to develop along a pathway that produces sperm.
2. They secrete *anti-Müllerian hormone*, which suppresses the development of the female reproductive tract by causing the Müllerian duct to regress (this duct otherwise gives rise to the oviduct, uterus, and upper part of the vagina).
3. They stimulate particular somatic cells that lie adjacent to the developing gonad to migrate into the gonad and form critical connective tissue structures that are required for normal sperm production.
4. They help to induce other somatic cells in the developing gonad to become *Leydig cells*, which secrete the male sex hormone *testosterone*; this hormone is responsible for inducing all male secondary sexual characteristics. These include the structures of the male reproductive tract, such as the prostate and seminal vesicles, which develop from another duct, called the Wolffian duct system. This duct system degenerates in the developing female because it requires testosterone to survive and develop. The testosterone also masculinizes the early developing brain and thereby plays a major part in determining male sexual identity and orientation, and thereby behavior: female rats that are treated with testosterone around birth, for example, later display malelike sexual behavior.

Sry encodes a gene-regulatory protein (Sry) that activates the transcription of other gene-regulatory proteins required for Sertoli cell development, including the Sry-related protein Sox9. In the absence of either Sry or Sox9, the genital ridge develops into an ovary. The supporting cells become *follicle cells* instead of Sertoli cells. Other somatic cells become *theca cells* instead of Leydig cells and, beginning at puberty secrete the female sex hormone *estrogen* instead of testosterone. The primordial germ cells develop into eggs instead of sperm (Figure 20-18, and see Figure 20-28), and the animal develops as a female.

If the genital ridges are removed before they have started to develop into testes or ovaries, a mammal develops into a female, regardless of the sex chromosomes it carries. It seems that female development is the "default" pathway of sexual development in mammals. [↑ TOP](#)

Summary

A small number of cells in the gastrulating mammalian embryo are signaled by their neighbors to become primordial germ cells. These cells migrate into the genital ridges, which develop into the gonads. Here, the primordial germ cells start to develop into either eggs, if the gonad is becoming an ovary, or sperm, if the gonad is becoming a testis. A developing gonad will develop into an ovary unless its somatic cells contain a Y chromosome, in which case it develops into a testis. The Sry gene on the Y chromosome is responsible for

this testis-determining function: it is expressed in a subset of somatic cells in the developing gonad, and it induces these cells to differentiate into Sertoli cells. The Sertoli cells in turn produce the signal molecules that promote the development of male characteristics, suppress the development of female characteristics, and induce the primordial germ cells to commit to sperm development. Figure 20-18. Influence of Sry on gonad development. The germ line cells are shaded in red, and the somatic cells are shaded in green and blue. The change from light to darker color indicates that the cell has matured or differentiated. The Sry gene acts in a subpopulation of somatic cells in the developing gonad to direct them to differentiate into Sertoli cells instead of into follicle cells. The Sertoli cells then induce primordial germ cells to commit to sperm development. They also secrete anti-Müllerian hormone, which causes the Müllerian duct to regress, and they help to induce other somatic cells to differentiate into Leydig cells, which secrete testosterone (see Figure 20-28). In the absence of Sry, the primordial germ cells

commit to egg development, and the somatic cells develop into either follicle cells, which support egg development, or theca cells, which secrete estrogen. Whereas Leydig cells begin secreting testosterone in the fetus, theca cells do not begin secreting estrogen until puberty.

Eggs

In one respect at least, eggs are the most remarkable of animal cells: once activated, they can give rise to a complete new individual within a matter of days or weeks. No other cell in a higher animal has this capacity. Activation is usually the consequence of *fertilization*—fusion of a sperm with the egg. In some organisms, however, the sperm itself is not strictly required, and an egg can be activated artificially by a variety of nonspecific chemical or physical treatments. Indeed, some organisms, including a few vertebrates such as some lizards, normally reproduce from eggs that become activated in the absence of sperm—that is, **parthenogenetically**.

Although an egg can give rise to every cell type in the adult organism, it is itself a highly specialized cell, uniquely equipped for the single function of generating a new individual. The cytoplasm of an egg can even reprogram a somatic cell nucleus so that the nucleus can direct the development of a new individual. That is how the famous sheep Dolly was produced. The nucleus of an unfertilized sheep egg was destroyed and replaced with the nucleus of an adult somatic cell. An electric shock was used to activate the egg, and the resulting embryo was implanted in the uterus of a surrogate mother. The resulting normal adult sheep had the genome of the donor somatic cell and was therefore a clone of the donor sheep.

In this section, we briefly consider some of the specialized features of an egg before discussing how it develops to the point of being ready for fertilization.

An Egg Is Highly Specialized for Independent Development, with Large Nutrient Reserves and an Elaborate Coat

The eggs of most animals are giant single cells, containing stockpiles of all the materials needed for initial development of the embryo through to the stage at which the new individual can begin feeding. Before the feeding stage, the giant cell cleaves into many smaller cells, but no net growth occurs. The mammalian embryo is an exception. It can start to grow early by taking up nutrients from the mother via the placenta. Thus, a mammalian egg, although still a large cell,

Search

Go

This book
books

All

PubMed

does not have to be as large as a frog or bird egg, for example. In general, eggs are typically spherical or ovoid, with a diameter of about 0.1 mm in humans and sea urchins (whose feeding larvae are tiny), 1 mm to 2 mm in frogs and fishes, and many centimeters in birds and reptiles ([Figure 20-19](#)). A typical somatic cell, by contrast, has a diameter of only about 10 or 20 μm ([Figure 20-20](#)).

The egg cytoplasm contains nutritional reserves in the form of yolk, which is rich in lipids, proteins, and polysaccharides and is usually contained within discrete structures called *yolk granules*. In some species, each yolk granule is membrane-enclosed, whereas in others it is not. In eggs that develop into large animals outside the mother's body, yolk can account for more than 95% of the volume of the cell. In mammals, whose embryos are largely nourished by their mothers, there is little, if any, yolk.

The **egg coat** is another peculiarity of eggs. It is a specialized form of extracellular matrix consisting largely of glycoprotein molecules, some secreted by the egg and others deposited on it by surrounding cells. In many species, the major coat is a layer immediately surrounding the egg plasma membrane; in nonmammalian eggs, such as those of sea urchins or chickens, it is called the *vitelline layer*, whereas in mammalian eggs it is called the *zona pellucida* ([Figure 20-21](#)). This layer protects the egg from mechanical damage, and in many eggs it also acts as a species-specific barrier to sperm, admitting only those of the same or closely related species.

Many eggs (including those of mammals) contain specialized secretory vesicles just under the plasma membrane in the outer region, or *cortex*, of the egg cytoplasm. When the egg is activated by a sperm, these cortical granules release their contents by exocytosis; the contents of the granules act to alter the egg coat so as to prevent more than one sperm from fusing with the egg (discussed below).

Cortical granules are usually distributed evenly throughout the egg cortex, but in some organisms other cytoplasmic components have a strikingly asymmetrical distribution. Some of these localized components later serve to help establish the polarity of the embryo, as discussed in [Chapter 21](#). [↑ TOP](#)

Eggs Develop in Stages

A developing egg is called an oocyte. Its differentiation into a mature egg (or *ovum*) involves a series of changes whose timing is geared to the steps of meiosis in which the germ cells go through their two final, highly specialized divisions. Oocytes have evolved special mechanisms for arresting progress through meiosis: they remain suspended in prophase I for a prolonged period while the oocyte grows in size, and in many cases they later arrest in metaphase II while awaiting fertilization (although they can arrest at various

other points, depending on the species).

While the details of oocyte development (oogenesis) vary from species to species, the general stages are similar, as outlined in Figure 20-22. Primordial germ cells migrate to the forming gonad to become *oogonia*, which proliferate by mitosis for a period before differentiating into *primary oocytes*. At this stage (usually before birth in mammals), the first meiotic division begins: the DNA replicates so that each chromosome consists of two sister chromatids, the duplicated homologous chromosomes pair along their long axes, and crossing-over occurs between nonsister chromatids of these paired chromosomes. After these events, the cell remains arrested in prophase of division I of meiosis (in a state equivalent, as we previously pointed out, to a G₂ phase of a mitotic division cycle) for a period lasting from a few days to many years, depending on the species. During this long period (or, in some cases, at the onset of sexual maturity), the primary oocytes synthesize a coat and cortical granules. In the case of large nonmammalian oocytes, they also accumulate ribosomes, yolk, glycogen, lipid, and the mRNA that will later direct the synthesis of proteins required for early embryonic growth and the unfolding of the developmental program. In many oocytes, the intensive biosynthetic activities are reflected in the structure of the chromosomes, which decondense and form lateral loops, taking on a characteristic "lampbrush" appearance, signifying that they are very busily engaged in RNA synthesis (see Figures 4-36 and 4-37).

The next phase of oocyte development is called *oocyte maturation*. It usually does not occur until sexual maturity, when the oocyte is stimulated by hormones. Under these hormonal influences, the cell resumes its progress through division I of meiosis. The chromosomes recondense, the nuclear envelope breaks down (this is generally taken to mark the beginning of maturation), and the replicated homologous chromosomes segregate at anaphase I into two daughter nuclei, each containing half the original number of chromosomes. To end division I, the cytoplasm divides asymmetrically to produce two cells that differ greatly in size: one is a small *polar body*, and the other is a large **secondary oocyte**, the precursor of the egg. At this stage, each of the chromosomes is still composed of two sister chromatids. These chromatids do not separate until division II of meiosis, when they are partitioned into separate cells, as previously described. After this final chromosome separation at anaphase II, the cytoplasm of the large secondary oocyte again divides asymmetrically to produce the mature egg (or **ovum**) and a second small polar body, each with a haploid set of single chromosomes (see Figure 20-22). Because of these two asymmetrical divisions of their cytoplasm, oocytes maintain their large size despite undergoing the two meiotic divisions. Both of the polar bodies are small, and they eventually degenerate.

In most vertebrates, oocyte maturation proceeds to metaphase of meiosis II and then arrests until fertilization. At ovulation, the arrested secondary oocyte is

released from the ovary and undergoes a rapid maturation step that transforms it into an egg that is prepared for fertilization. If fertilization occurs, the egg is stimulated to complete meiosis. [↑ TOP](#)

Oocytes Use Special Mechanisms to Grow to Their Large Size

A somatic cell with a diameter of 10–20 μm typically takes about 24 hours to double its mass in preparation for cell division. At this rate of biosynthesis, such a cell would take a very long time to reach the thousand-fold greater mass of a mammalian egg with a diameter of 100 μm . It would take even longer to reach the million-fold greater mass of an insect egg with a diameter of 1000 μm . Yet some insects live only a few days and manage to produce eggs with diameters even greater than 1000 μm . It is clear that eggs must have special mechanisms for achieving their large size.

One simple strategy for rapid growth is to have extra gene copies in the cell. Thus, the oocyte delays completion of the first meiotic division so as to grow while it contains the diploid chromosome set in duplicate. In this way, it has twice as much DNA available for RNA synthesis as does an average somatic cell in the G_1 phase of the cell cycle. The oocytes of some species go to even greater lengths to accumulate extra DNA: they produce many extra copies of certain genes. We discuss in [Chapter 6](#) how the somatic cells of most organisms require 100 to 500 copies of the ribosomal RNA genes in order to produce enough ribosomes for protein synthesis. Eggs require even greater numbers of ribosomes to support protein synthesis during early embryogenesis, and in the oocytes of many animals the ribosomal RNA genes are specifically amplified; some amphibian eggs, for example, contain 1 or 2 million copies of these genes.

Oocytes may also depend partly on the synthetic activities of other cells for their growth. Yolk, for example, is usually synthesized outside the ovary and imported into the oocyte. In birds, amphibians, and insects, yolk proteins are made by liver cells (or their equivalents), which secrete these proteins into the blood. Within the ovaries, oocytes take up the yolk proteins from the extracellular fluid by receptor-mediated endocytosis (see [Figure 13-41](#)).

Nutritive help can also come from neighboring accessory cells in the ovary. These can be of two types. In some invertebrates, some of the progeny of the oogonia become [nurse cells](#) instead of becoming oocytes. These cells usually are connected to the oocyte by cytoplasmic bridges through which macromolecules can pass directly into the oocyte cytoplasm ([Figure 20-23](#)). For the insect oocyte, the nurse cells manufacture many of the products—ribosomes, mRNA, protein, and so on—that vertebrate oocytes have to manufacture for themselves.

The other accessory cells in the ovary that help to nourish developing oocytes

are ordinary somatic cells called follicle cells, which are found in both invertebrates and vertebrates. They are arranged as an epithelial layer around the oocyte (Figure 20-24, and see Figure 20-23), to which they are connected only by gap junctions, which permit the exchange of small molecules but not macromolecules. While these cells are unable to provide the oocyte with preformed macromolecules through these communicating junctions, they may help to supply the smaller precursor molecules from which macromolecules are made. In addition, follicle cells frequently secrete macromolecules that contribute to the egg coat, or are taken up by receptor-mediated endocytosis into the growing oocyte, or act on egg cell-surface receptors to control the spatial patterning and axial asymmetries of the egg (discussed in Chapter 21). [↑ TOP](#)

Summary

Eggs develop in stages from primordial germ cells that migrate into the developing gonad early in development to become oogonia. After mitotic proliferation, oogonia become primary oocytes, which begin meiotic division I and then arrest at prophase I for days to years, depending on the species. During this prophase-I arrest period, primary oocytes grow, synthesize a coat, and accumulate ribosomes, mRNAs, and proteins, often enlisting the help of other cells, including surrounding accessory cells. In the process of maturation, primary oocytes complete meiotic division I to form a small polar body and a large secondary oocyte, which proceeds into metaphase of meiotic division II. There, in many species, the oocyte is arrested until stimulated by fertilization to complete meiosis and begin embryonic development. [↑ TOP](#)

Figure 20-22. The stages of oogenesis. Oogonia develop from primordial germ cells that migrate into the developing gonad early in embryogenesis. After a number of mitotic divisions, oogonia begin meiotic division I, after which they are called primary oocytes. In mammals, primary oocytes are formed very early (between 3 and 8 months of gestation in the human embryo) and remain arrested in prophase of meiotic division I until the female becomes sexually mature. At this point, a small number periodically mature under the influence of hormones, completing meiotic division I to become secondary oocytes, which eventually undergo meiotic division II to become mature eggs (ova). The stage at which the egg or oocyte is released from the ovary and is fertilized varies from species to species. In most vertebrates, oocyte maturation is arrested at metaphase of meiosis II and the secondary oocyte completes meiosis II only after fertilization. All of the polar bodies eventually degenerate. In most animals, the developing oocyte is surrounded by specialized accessory cells that help to isolate and nourish it (not shown).

Figure 20-23. Nurse cells and follicle cells associated with a *Drosophila* oocyte. The nurse cells and the oocyte arise from a common oogonium, which gives rise to one oocyte and 15 nurse cells (only 7 of which are seen in this plane of section). These cells remain joined by cytoplasmic bridges, which result from incomplete cell division. Eventually the nurse cells dump their cytoplasmic contents into the developing oocyte and then kill themselves. The follicle cells develop independently (from mesodermal cells).

Sperm

In most species, there are just two types of gamete, and they are radically different. The egg is among the largest cells in an organism, while the sperm (**spermatozoon**, plural **spermatozoa**) is often the smallest. The egg and the sperm are optimized in opposite ways for the propagation of the genes they carry. The egg is nonmotile and aids the survival of the maternal genes by providing large stocks of raw materials for growth and development, together with an effective protective wrapping. The sperm, by contrast, is optimized to propagate the paternal genes by exploiting this maternal investment: it is usually highly motile and streamlined for speed and efficiency in the task of fertilization. Competition between sperm is fierce, and the vast majority fail in their mission: of the billions of sperm released during the reproductive life of a human male, only a few ever manage to fertilize an egg.

Sperm Are Highly Adapted for Delivering Their DNA to an Egg

Typical sperm are "stripped-down" cells, equipped with a strong flagellum to propel them through an aqueous medium but unencumbered by cytoplasmic organelles such as ribosomes, endoplasmic reticulum, or Golgi apparatus, which are unnecessary for the task of delivering the DNA to the egg. Sperm, however, contain many mitochondria strategically placed where they can most efficiently power the flagellum. Sperm usually consist of two morphologically and functionally distinct regions enclosed by a single plasma membrane: the *tail*, which propels the sperm to the egg and helps it to burrow through the egg coat, and the *head*, which contains a condensed haploid nucleus (Figure 20-25). The DNA in the nucleus is extremely tightly packed, so that its volume is minimized for transport, and transcription is shut down. The chromosomes of many sperm have dispensed with the histones of somatic cells and are packed instead with simple, highly positively charged proteins called *protamines*.

In the head of most animal sperm, closely apposed to the anterior end of the nuclear envelope, is a specialized secretory vesicle called the acrosomal vesicle (see Figure 20-25). This vesicle contains hydrolytic enzymes that may

This book
books
PubMed

All

help the sperm to penetrate the egg's outer coat. When a sperm contacts an egg, the contents of the vesicle are released by exocytosis in the so-called *acrosome reaction*; in some sperm, this reaction also exposes or releases specific proteins that help bind the sperm tightly to the egg coat.

The motile tail of a sperm is a long flagellum, whose central axoneme emanates from a basal body situated just posterior to the nucleus. As described in [Chapter 16](#), the axoneme consists of two central singlet microtubules surrounded by nine evenly spaced microtubule doublets. The flagellum of some sperm (including those of mammals) differs from other flagella in that the usual $9 + 2$ pattern of the axoneme is further surrounded by nine outer dense fibers ([Figure 20-26](#)). These dense fibers are stiff and noncontractile, and it is not known what role they have in the active bending of the flagellum, which is caused by the sliding of adjacent microtubule doublets past one another. Flagellar movement is driven by dynein motor proteins, which use the energy of ATP hydrolysis to slide the microtubules, as discussed in [Chapter 16](#). The ATP is generated by highly specialized mitochondria in the anterior part of the sperm tail (called the *midpiece*), where the ATP is needed (see [Figures 20-25](#) and [20-26](#)). [↑ TOP](#)

Sperm Are Produced Continuously in Most Mammals

In mammals, there are major differences in the way in which eggs are produced (oogenesis) and the way in which sperm are produced ([spermatogenesis](#)). In human females, for example, oogonia proliferate only in the fetus, enter meiosis before birth, and become arrested as oocytes in the first meiotic prophase, in which state they may remain for up to 50 years. Individual oocytes mature from this strictly limited stock and are ovulated at intervals, generally one at a time, beginning at puberty. In human males, by contrast, meiosis and spermatogenesis do not begin in the testes until puberty and then go on continuously in the epithelial lining of very long, tightly coiled tubes, called *seminiferous tubules*. Immature germ cells, called *spermatogonia* (singular, *spermatogonium*), are located around the outer edge of these tubes next to the basal lamina, where they proliferate continuously by mitosis. Some of the daughter cells stop proliferating and differentiate into *primary spermatocytes*. These cells enter the first meiotic prophase, in which their paired homologous chromosomes participate in crossing-over, and then proceed with division I of meiosis to produce two *secondary spermatocytes*, each containing 22 duplicated autosomal chromosomes and either a duplicated X or a duplicated Y chromosome. The two secondary spermatocytes derived from each primary spermatocyte proceed through meiotic division II to produce four *spermatids*, each with a haploid number of single chromosomes. These haploid spermatids then undergo morphological differentiation into sperm ([Figure 20-27](#)), which escape into the lumen of the seminiferous tubule ([Figure 20-28](#)). The sperm subsequently pass into the *epididymis*, a coiled tube overlying the testis, where they undergo further maturation and are stored.

An intriguing feature of spermatogenesis is that the developing male germ cells fail to complete cytoplasmic division (cytokinesis) during mitosis and meiosis. Consequently, large clones of differentiating daughter cells that have descended from one maturing spermatogonium remain connected by cytoplasmic bridges, forming a syncytium ([Figure 20-29](#)). The cytoplasmic bridges persist until the very end of sperm differentiation, when individual sperm are released into the tubule lumen. This accounts for the observation that mature sperm arise synchronously in any given area of a seminiferous tubule. But what is the function of the syncytial arrangement?

Unlike oocytes, sperm undergo most of their differentiation after their nuclei have completed meiosis to become haploid. The presence of cytoplasmic bridges between them, however, means that each developing haploid sperm shares a common cytoplasm with its neighbors. In this way, it can be supplied with all the products of a complete diploid genome. Developing sperm that carry a Y chromosome, for example, can be supplied with essential proteins encoded by genes on the X chromosome. Thus, the diploid genome directs sperm differentiation just as it directs egg differentiation.

Some of the genes that regulate spermatogenesis have been conserved in evolution from flies to humans. The *DAZ* gene, for example, which encodes an RNA-binding protein and is located on the Y chromosome, is deleted in many infertile men, many of whom cannot make sperm. Two *Drosophila* genes that are homologous to *DAZ* are essential for spermatogenesis in the fly. RNA-binding proteins are especially important in spermatogenesis, because many of the genes expressed in the sperm lineage are regulated at the level of RNA translation. [↑ TOP](#)

Summary

A sperm is usually a small, compact cell, highly specialized for the task of fertilizing an egg. Whereas in human females the total pool of oocytes is produced before birth, in males new germ cells enter meiosis continually from the time of sexual maturation, with each diploid primary spermatocyte giving rise to four haploid mature sperm. The process of sperm differentiation occurs after meiosis is complete, requiring five weeks in humans. Because the maturing spermatogonia and spermatocytes fail to complete cytokinesis, however, the progeny of a single spermatogonium develop as a large syncytium. Sperm differentiation is therefore directed by the products from both parental chromosomes, even though each nucleus is haploid. [↑ TOP](#)

Figure 20-27. The stages of spermatogenesis. Spermatogonia develop from primordial germ cells that migrate into the testis early in embryogenesis. When the animal becomes sexually mature, the spermatogonia begin to proliferate rapidly, generating some progeny that retain the capacity to continue dividing indefinitely (as stem-cell spermatogonia) and other progeny (maturing spermatogonia) that will, after a limited number of further mitotic division cycles, embark on meiosis to become primary spermatocytes. The primary spermatocytes continue through meiotic division I to become secondary spermatocytes. After they complete meiotic division II, the secondary spermatocytes produce haploid spermatids, which differentiate into mature sperm (spermatozoa). Spermatogenesis differs from oogenesis (see [Figure 20-22](#)) in several ways. (1) New cells enter meiosis continually from the time of puberty. (2) Each cell that begins meiosis gives rise to four mature gametes rather than one. (3) Mature sperm form by an elaborate process of cell differentiation that begins after meiosis is complete. (4) About twice as many cell divisions occur in the production of a sperm as in the production of an egg; in a mouse, for example, it is estimated that on average about 56 divisions occur from zygote to mature sperm, and about 27 divisions occur from zygote to mature egg.

Figure 20-28. Highly simplified drawing of a cross section of a seminiferous tubule in a mammalian testis. (A) All of the stages of spermatogenesis shown take place while the developing gametes are in intimate association with Sertoli cells. These large cells extend from the basal lamina to the lumen of the seminiferous tubule; they are required for the survival of the germ cells and are analogous to follicle cells in the ovary (see [Figure 20-18](#)). Spermatogenesis also depends on testosterone secreted by Leydig cells, located between the seminiferous tubules. (B) Some of these cells are self-renewing stem-cell spermatogonia, whereas others are maturing spermatogonia; after a number of mitotic divisions, the maturing spermatogonia stop dividing by mitosis and enter meiosis to become primary spermatocytes. Eventually, sperm are released into the lumen. In man, it takes about 24 days for a spermatocyte to complete meiosis to become a spermatid and another 5 weeks for a spermatid to develop into a sperm. Sperm undergo further maturation and become motile in the epididymis; only then are they fully mature sperm.

Figure 20-29. Cytoplasmic bridges in developing sperm cells and their precursors. The progeny of a single maturing spermatogonium remain connected to one another by cytoplasmic bridges throughout their differentiation into mature sperm. For the sake of simplicity, only two connected maturing spermatogonia are shown entering meiosis, eventually to form eight connected haploid spermatids. In fact, the number of connected cells that go through two meiotic divisions and differentiate synchronously is very much larger than shown here. Note that in the process of differentiating, most of the spermatid cytoplasm is discarded as residual bodies.

Fertilization

Once released, egg and sperm alike are destined to die within minutes or hours unless they find each other and fuse in the process of fertilization. Through fertilization, the egg and sperm are saved: the egg is activated to begin its developmental program, and the haploid nuclei of the two gametes come together to form the genome of a new diploid organism. The mechanism of fertilization has been most intensively studied in marine invertebrates, especially sea urchins. In these organisms fertilization occurs in sea water, into which huge numbers of both sperm and eggs are released. Such *external fertilization* has been more accessible to study than the internal fertilization of mammals, which normally occurs in the female reproductive tract after mating.

In the late 1950s, however, it became possible to fertilize mammalian eggs *in vitro*, opening the way to an analysis of the cellular and molecular events in mammalian fertilization. Progress in understanding mammalian fertilization has brought substantial medical benefit: mammalian eggs that have been fertilized *in vitro* can develop into normal individuals when transplanted into the uterus; in this way many previously infertile women have been able to produce normal children. As mentioned earlier, it is possible to use *in vitro* fertilization to produce a clone of a sheep, a pig, or a mouse by transferring the nucleus of one of its somatic cells into an unfertilized egg that has had its own nucleus removed or destroyed. There is no reason to doubt that a human could be cloned in the same way, although there are serious ethical arguments about whether this should ever be done, especially as the likelihood of producing an abnormal child is very high. In this section, we focus our discussion on the fertilization of mammalian eggs.

Species-Specific Binding to the Zona Pellucida Induces the Sperm to Undergo an Acrosome Reaction

Of the 300,000,000 human sperm ejaculated during coitus, only about 200 reach the site of fertilization in the oviduct. There is evidence that chemical signals released by the follicle cells that surround the ovulated egg attract the sperm to the egg, but the nature of the chemoattractant molecules is unknown. Once it finds an egg, the sperm must first migrate through the layer of follicle

All

cells and then bind to and cross the egg coat—the *zona pellucida*. Finally, the sperm must bind to and fuse with the egg plasma membrane. To become competent to accomplish these tasks, ejaculated mammalian sperm must normally be modified by conditions in the female reproductive tract, a process called capacitation, which requires about 5–6 hours in humans. Capacitation is triggered by bicarbonate ions (HCO_3^-) in the vagina, which enter the sperm and directly activate a soluble adenylyl cyclase enzyme in the cytosol. The cyclase produces cyclic AMP (discussed in Chapter 15), which helps to initiate the changes associated with capacitation. Capacitation alters the lipid and glycoprotein composition of the sperm plasma membrane, increases sperm metabolism and motility, and markedly decreases the membrane potential (that is, the membrane potential moves to a more negative value so that the membrane becomes hyperpolarized).

Once a capacitated sperm has penetrated the layer of follicle cells, it binds to the *zona pellucida* (see Figure 20-21). The zona usually acts as a barrier to fertilization across species, and removing it often eliminates this barrier. Human sperm, for example, will fertilize hamster eggs from which the zona has been removed with specific enzymes; not surprisingly, such hybrid zygotes fail to develop. Zona-free hamster eggs, however, are sometimes used in infertility clinics to assess the fertilizing capacity of human sperm *in vitro* (Figure 20-30).

The zona pellucida of mammalian eggs is composed mainly of three glycoproteins, all of which are produced exclusively by the growing oocyte. Two of them, ZP2 and ZP3, assemble into long filaments, while the other, ZP1, cross-links the filaments into a three-dimensional network. The protein ZP3 is crucial: female mice with an inactivated ZP3 gene produce eggs lacking a zona and are infertile. ZP3 is responsible for the species-specific binding of sperm to the zona, at least in mice. Several proteins on the sperm surface that bind to specific O-linked oligosaccharides on ZP3 have been implicated as ZP3 receptors, but the contribution of each is uncertain. On binding to the zona, the sperm is induced to undergo the acrosome reaction, in which the contents of the acrosome are released by exocytosis (Figure 20-31). In the mouse, at least, the trigger for the acrosome reaction is ZP3 in the zona, which induces an influx of Ca^{2+} into the sperm cytosol; this in turn initiates exocytosis. An increase in cytosolic Ca^{2+} seems to be necessary and sufficient to trigger the acrosome reaction in all animals.

The acrosome reaction is required for fertilization. It exposes various hydrolytic enzymes that help the sperm tunnel through the zona pellucida, and it exposes other proteins on the sperm surface that bind to the ZP2 protein and thereby help the sperm maintain its tight binding to the zona while burrowing through it. In addition, the acrosome reaction exposes proteins in the sperm plasma membrane that mediate the binding and fusion of this membrane with that of the egg, as we discuss below. Although fertilization normally occurs by sperm—egg fusion, it can also be achieved artificially, by injecting the sperm

into the egg cytoplasm; this is sometimes done in infertility clinics when there is a problem with sperm—egg fusion. [↑ TOP](#)

The Egg Cortical Reaction Helps to Ensure That Only One Sperm Fertilizes the Egg

Although many sperm can bind to an egg, normally only one fuses with the egg plasma membrane and injects its nucleus and other organelles into the egg cytoplasm. If more than one sperm fuses—a condition called *polyspermy*—multipolar or extra mitotic spindles are formed, resulting in faulty segregation of chromosomes during cell division; nondiploid cells are produced, and development usually stops. Two mechanisms can operate to ensure that only one sperm fertilizes the egg. In many cases, a rapid depolarization of the egg plasma membrane, which is caused by the fusion of the first sperm, prevents further sperm from fusing and thereby acts as a fast *primary block to polyspermy*. But the membrane potential returns to normal soon after fertilization, so that a second mechanism is required to ensure a longer-term, *secondary block to polyspermy*. This is provided by the egg **cortical reaction**.

When the sperm fuses with the egg plasma membrane, it causes a local increase in cytosolic Ca^{2+} , which spreads through the cell in a wave. In some mammalian eggs, the initial increase in Ca^{2+} is followed by prolonged Ca^{2+} oscillations. There is evidence that the Ca^{2+} wave or oscillations are induced by a protein that is introduced into the egg by the sperm, but the nature of the protein is unknown.

The Ca^{2+} wave or oscillations activate the egg to begin development, and they initiate the cortical reaction, in which the cortical granules release their contents by exocytosis. If the cytosolic concentration of Ca^{2+} is increased artificially—either directly by an injection of Ca^{2+} or indirectly by the use of Ca^{2+} -carrying ionophores (discussed in [Chapter 11](#))—the eggs of all animals so far tested, including mammals, are activated. Conversely, preventing the increase in Ca^{2+} by injecting the Ca^{2+} chelator EGTA inhibits activation of the egg in response to fertilization. The contents of the cortical granules include various enzymes that are released by the cortical reaction and change the structure of the zona pellucida. The altered zona becomes "hardened," so that sperm no longer bind to it, and it therefore provides a block to polyspermy. Among the changes that occur in the zona is the proteolytic cleavage of ZP2 and the hydrolysis of sugar groups on ZP3 ([Figure 20-32](#)). [↑ TOP](#)

The Mechanism of Sperm—Egg Fusion Is Still Unknown

After a sperm has penetrated the extracellular coat of the egg, it interacts with the egg plasma membrane overlying the tips of microvilli on the egg surface (see [Figure 20-30](#)). Neighboring microvilli then rapidly elongate and cluster

around the sperm to ensure that it is held firmly so that it can fuse with the egg. After fusion, the entire sperm is drawn head-first into the egg as the microvilli are resorbed. In mouse sperm, a transmembrane protein called *fertilin*, which becomes exposed on the sperm surface during the acrosome reaction, helps the sperm bind to the egg plasma membrane and may also have a role in the fusion of the two plasma membranes.

Fertilin is composed of two glycosylated transmembrane subunits called α and β , which are held together by noncovalent bonds (Figure 20-33). The extracellular N-terminal domain of the fertilin subunits is thought to bind to integrins in the egg plasma membrane and thereby help the sperm adhere to the egg membrane in preparation for fusion. The integrin in the egg plasma membrane is associated with a member of the *tetraspan* family of membrane proteins—so-called because they have four membrane-spanning segments. Female mice that are deficient in this protein are infertile, as their eggs cannot fuse with sperm. The extracellular domain of the α subunit of fertilin contains a hydrophobic region that resembles the fusogenic region of viral fusion proteins, which mediates the fusion of enveloped viruses with the cells that they infect (discussed in Chapter 13). Synthetic peptides corresponding to this region of the fertilin α chain can induce membrane fusion in a test-tube, consistent with the possibility that fertilin helps to mediate sperm—egg fusion.

Male mice that are fertilin-deficient are infertile, and their sperm are eightfold less efficient than normal sperm in binding to the egg plasma membrane but only 50% less efficient in fusing with it. Surprisingly, these defects do not seem to be the main cause of the infertility. The fertilin-deficient sperm are even more impaired in their ability to bind to the zona pellucida and to migrate out of the uterus into the oviduct, where the egg is normally fertilized. Clearly, fertilin's roles in fertilization are more complex than originally suspected and are still not completely understood. The finding that fertilin-deficient sperm can still fertilize eggs in a test tube, albeit inefficiently, suggests that other sperm proteins normally help to mediate sperm binding and fusion to the egg plasma membrane.

As the cell biology of mammalian fertilization becomes better understood and the molecules that mediate the various steps in the process are defined, new strategies for contraception become possible. One approach currently being investigated, for example, is to immunize males or females with molecules that are required for reproduction in the hope that the antibodies produced will inhibit the activities of these molecules. In addition to the various hormones and hormone receptors involved in reproduction, ZP3 and fertilin might be appropriate target molecules. An alternative approach would be to administer oligosaccharides or peptides corresponding to ligands that operate in fertilization, such as the postulated integrin-binding domain of fertilin. Small molecules of this type block fertilization in a test-tube by competing with the normal ligand for its receptor.  [TOP](#)

The Sperm Provides a Centriole for the Zygote

Once fertilized, the egg is called a zygote. Fertilization is not complete, however, until the two haploid nuclei (called *pronuclei*) have come together and combined their chromosomes into a single diploid nucleus. In fertilized mammalian eggs, the two pronuclei do not fuse directly as they do in many other species. They approach each other but remain distinct until after the membrane of each pronucleus has broken down in preparation for the zygote's first mitotic division (Figure 20-34).

In most animals, including humans, the sperm contributes more than DNA to the zygote. It also donates a centriole—an organelle that is lacking in unfertilized human eggs. The sperm centriole enters the egg along with the sperm nucleus and tail and a centrosome forms around it. In humans, it replicates and helps organize the assembly of the first mitotic spindle in the zygote (Figure 20-35). This explains why multipolar or extra mitotic spindles form in cases of polyspermy, where several sperm contribute their centrioles to the egg.

Fertilization marks the beginning of one of the most remarkable phenomena in all of biology—the process of embryogenesis, in which the zygote develops into a new individual. This is the subject of the next chapter. [↑ TOP](#)

Summary

Mammalian fertilization begins when the head of a sperm binds in a species-specific manner to the zona pellucida surrounding the egg. This induces the acrosome reaction in the sperm, which releases the contents of its acrosomal vesicle, exposing enzymes that help the sperm to digest its way through the zona to the egg plasma membrane in order to fuse with it. The fusion of the sperm with the egg induces a Ca^{2+} signal in the egg. The Ca^{2+} signal activates the egg to undergo the cortical reaction, in which cortical granules release their contents, including enzymes that alter the zona pellucida and thereby prevent the fusion of additional sperm. The Ca^{2+} signal also triggers the development of the zygote, which begins after sperm and egg haploid pronuclei have come together, and their chromosomes have aligned on a single mitotic spindle, which mediates the first division of the zygote. Figure 20-31. The acrosome reaction that occurs when a mammalian sperm fertilizes an egg. In mice, a single glycoprotein in the zona pellucida, ZP3, is thought to be responsible for both binding the sperm and inducing the acrosome reaction. Note that a mammalian sperm interacts tangentially with the egg plasma membrane so that fusion occurs at the equator, rather than at the tip, of the sperm head. In mice, the zona pellucida is about 6 μm thick, and sperm cross it at a rate of about 1 $\mu\text{m}/\text{min}$.

Figure 20-32. How the cortical reaction in a mouse egg is thought to prevent additional sperm from entering the egg. The released contents of the cortical granules both remove carbohydrate from ZP3 so it no longer can bind to the sperm plasma membrane and partly cleave ZP2, hardening the zona pellucida. Together these changes provide a block to polyspermy.

Figure 20-33. The fertilin protein in the sperm plasma membrane. The α and β subunits, which are both glycosylated (not shown), are noncovalently associated. Both subunits belong to the ADAM family of proteins, which includes proteins thought to function in either cell adhesion or the proteolytic processing of other transmembrane proteins (such as Notch, which is discussed in [Chapter 15](#)). The proteolytic domain that is normally present at the amino terminus of these proteins is removed from the fertilin protein during sperm maturation.

Molecular Biology of the Cell → V. Cells in Their Social Context

21. Development of Multicellular Organisms

An animal or plant starts its life as a single cell—a fertilized egg. During development, this cell divides repeatedly to produce many different cells in a final pattern of spectacular complexity and precision. Ultimately, the genome determines the pattern, and the puzzle of developmental biology is to understand how it does so.

The genome is normally identical in every cell; the cells differ not because they contain different genetic information, but because they express different sets of genes. This selective gene expression controls the four essential processes by which the embryo is constructed: (1) *cell proliferation*, producing many cells from one, (2) *cell specialization*, creating cells with different characteristics at different positions, (3) *cell interactions*, coordinating the behavior of one cell with that of its neighbors, and (4) *cell movement*, rearranging the cells to form structured tissues and organs ([Figure 21-1](#)).

In a developing embryo, all these processes are happening at once, in a kaleidoscopic variety of different ways in different parts of the organism. To understand the basic strategies of development, we have to narrow our focus. In particular, we must understand the course of events from the standpoint of the individual cell and the way the genome acts within it. There is no commanding officer standing above the fray to direct the troops; each of the millions of cells in the embryo has to make its own decisions, according to its own copy of the genetic instructions and its own particular circumstances.

The complexity of animals and plants depends on a remarkable feature of the genetic control system. Cells have a memory: the genes a cell expresses and the way it behaves depend on the cell's past as well as its present environment. The cells of your body—the muscle cells, the neurons, the skin cells, the gut cells, and so on—maintain their specialized characters not because they continually receive the same instructions from their surroundings, but because they retain a record of signals their ancestors received in early embryonic development. The molecular mechanisms of cell memory have been introduced in [Chapter 7](#). In this chapter we shall encounter its consequences. [↑ TOP](#)

Development of Multicellular Organisms

Universal Mechanisms of Animal Development

There are about ten million species of animals, and they are fantastically varied. One would no more expect the worm, the flea, the eagle and the giant squid all to be generated by the same developmental mechanisms, than one would suppose that the same methods were used to make a shoe and an airplane. Some similar abstract principles might be involved, perhaps, but surely not the same specific molecules?

One of the most astonishing revelations of the past ten or twenty years has been that our initial suspicions are wrong. In fact, much of the basic machinery of development is essentially the same, not just in all vertebrates but in all the major phyla of invertebrates too. Recognizably similar, evolutionarily related molecules define our specialized cell types, mark the differences between body regions, and help create the body's pattern. Homologous proteins are often functionally interchangeable between very different species. A mouse protein produced artificially in a fly can often perform the same function as the fly's own version of that protein, and vice versa, successfully controlling the development of an eye, for example, or the architecture of the brain ([Figure 21-2](#)). Thanks to this underlying unity of mechanism, as we shall see, developmental biologists are now well on their way toward a coherent understanding of animal development.

Plants are a separate kingdom: they have evolved their multicellular organization independently of animals. For their development too, a unified account can be given, but it is different from that for animals. Animals will be our main concern in this chapter, but we shall return to plants briefly at the end.

We begin by reviewing some of the basic general principles of animal development and by introducing the seven animal species that developmental biologists have adopted as their chief model organisms.

Animals Share Some Basic Anatomical Features

The similarities between animal species in the genes that control development reflect the evolution of animals from a common ancestor in which these genes

were already present. Although we do not know what it looked like, the common ancestor of worms, molluscs, insects, vertebrates, and other complex animals must have had many differentiated cell types that would be recognizable to us: epidermal cells, for example, forming a protective outer layer; gut cells to absorb nutrients from ingested food; muscle cells to move; neurons and sensory cells to control the movements. The body must have been organized with a sheet of skin covering the exterior, a mouth for feeding and a gut tube to contain and process the food—with muscles, nerves and other tissues arranged in the space between the external sheet of skin and the internal gut tube.

These features are common to almost all animals, and they correspond to a common basic anatomical scheme of development. The egg cell—a giant storehouse of materials—divides, or **cleaves**, to form many smaller cells. These cohere to create an epithelial sheet facing the external medium. Much of this sheet remains external, constituting the ectoderm—the precursor of the epidermis and of the nervous system. A part of the sheet becomes tucked into the interior to form endoderm—the precursor of the gut and its appendages, such as lung and liver. Another group of cells move into the space between ectoderm and endoderm, and form the mesoderm—the precursor of muscles, connective tissues, and various other components. This transformation of a simple ball or hollow sphere of cells into a structure with a gut is called gastrulation (from the Greek word for a belly), and in one form or another it is an almost universal feature of animal development. Figure 21-3 illustrates the process as it is seen in the sea urchin.

Evolution has diversified upon the molecular and anatomical fundamentals that we describe in this chapter to produce the wonderful variety of present-day species. But the underlying conservation of genes and mechanisms means that studying the development of one animal very often leads to general insights into the development of many other types of animals. As a result, developmental biologists today, like cell biologists, have the luxury of addressing fundamental questions in whatever species offers the easiest path to an answer.  [TOP](#)

Multicellular Animals Are Enriched in Proteins Mediating Cell Interactions and Gene Regulation

Genome sequencing reveals the extent of molecular similarities between species. The nematode worm *Caenorhabditis elegans*, the fly *Drosophila melanogaster*, and the vertebrate *Homo sapiens* are the first three animals for which a complete genome sequence was obtained. In the family tree of animal evolution, they are very distant from one another: the lineage leading to the vertebrates is thought to have diverged from that leading to the nematodes, insects and molluscs more than 600 million years ago. Nevertheless, when the 19,000 genes of *C. elegans*, the 14,000 genes of *Drosophila*, and the 30,000 genes of the human are systematically compared with one another, it is found

 Table 21-1. Some Signal Proteins That Are...	
---	--

that about 50% of the genes in each of these species have clearly recognizable homologs in one or both of the other two species. In other words, recognizable versions of at least 50% of all human genes were already present in the common ancestor of worms, flies, and humans.

This book	All
books	
PubMed	

Of course, not everything is conserved: there are some genes with key roles in vertebrate development that have no homologs in the genome of *C. elegans* or *Drosophila*, and vice versa. However, a large proportion of the 50% of genes that lack identifiable homologs in other phyla may do so simply because their functions are of minor importance. Although these nonconserved genes are transcribed and well represented in cDNA libraries, studies of DNA and amino acid sequence variability in and between natural populations indicate that these genes are unusually free to mutate without seriously harming fitness. Because they are free to evolve so rapidly, a few tens of millions of years may be enough to obliterate any family resemblance or to permit loss from the genome.

The genomes of different classes of animals differ also because, as discussed in [Chapter 1](#), there are substantial variations in the extent of gene duplication: the amount of gene duplication in the evolution of the vertebrates has been particularly large, with the result that a mammal or a fish often has several homologs corresponding to a single gene in a worm or a fly.

Despite such differences, to a first approximation we can say that all these animals have a similar set of proteins at their disposal for their key functions. In other words, they construct their bodies using roughly the same molecular kit of parts.

What genes, then, are needed to produce a multicellular animal, beyond those necessary for a solitary cell? Comparison of animal genomes with that of budding yeast—a unicellular eucaryote—suggests that two classes of proteins are especially important for multicellular organization. The first class is that of the transmembrane molecules used for cell adhesion and cell signaling. As many as 2000 *C. elegans* genes encode cell surface receptors, cell adhesion proteins, and ion channels that are either not present in yeast or present in much smaller numbers. The second class is that of gene regulatory proteins: these DNA-binding proteins are much more numerous in the *C. elegans* genome than in yeast. For example, the basic helix-loop-helix family has 41 members in *C. elegans*, 84 in *Drosophila*, 131 in humans and only 7 in yeast, and other families of regulators of gene expression are also dramatically overrepresented in animals as compared to yeast. Not surprisingly, these two classes of proteins are central to developmental biology: as we shall see, the development of multicellular animals is dominated by cell-cell interactions and by differential gene expression. [↑ TOP](#)

Regulatory DNA Defines the Program of Development

The fundamental similarity in the gene sets of different animals amazed

developmental biologists when it was first discovered. A worm, a fly, a mollusc and a mammal do indeed share many of the same essential cell types, and they do all have a mouth, a gut, a nervous system and a skin; but beyond a few such basic features they seem radically different in their body structure. If the genome determines the structure of the body and these animals all have such a similar collection of genes, how can they be so different?

The proteins encoded in the genome can be viewed as the components of a construction kit. Many things can be built with this kit, just as a child's construction kit can be used to make trucks, houses, bridges, cranes, and so on by assembling the components in different combinations. Some components necessarily go together—nuts with bolts, wheels with tires and axles—but the large-scale organization of the final object is not defined by these substructures. Rather, it is defined by the instructions that accompany the components and prescribe how they are to be assembled.

To a large extent, the instructions needed to produce a multicellular animal are contained in the non-coding, regulatory DNA that is associated with each gene. As discussed in [Chapter 4](#), each gene in a multicellular organism is associated with thousands or tens of thousands of nucleotides of noncoding DNA. This DNA may contain, scattered within it, dozens of separate regulatory elements or *enhancers*—short DNA segments that serve as binding sites for specific complexes of gene regulatory proteins. Roughly speaking, as explained in [Chapter 7](#), the presence of a given regulatory module of this sort leads to expression of the gene whenever the complex of proteins recognizing that segment of DNA is appropriately assembled in the cell (in some cases, an inhibition or a more complicated effect on gene expression is produced instead). If we could decipher the full set of regulatory modules associated with a gene, we would understand all the different molecular conditions under which the product of that gene is to be made. This regulatory DNA can therefore be said to define the sequential program of development: the rules for stepping from one state to the next, as the cells proliferate and read their positions in the embryo by reference to their surroundings, switching on new sets of genes according to the activities of the proteins that they currently contain ([Figure 21-4](#)).

When we compare animal species with similar body plans—different vertebrates such as a fish, a bird and a mammal, for example—we find that corresponding genes usually have similar sets of regulatory modules: the DNA sequences of many of the individual modules have been well conserved and are recognizably homologous in the different animals. The same is true if we compare different species of nematode worm, or different species of insect. But when we compare vertebrate regulatory regions with those of worm or fly, it is hard to see any such resemblance. The protein-coding sequences are unmistakably similar, but the corresponding regulatory DNA sequences appear very different. This is the expected result if different body plans are produced mainly by changing the program embodied in the regulatory DNA, while retaining most of the same kit of proteins. [↑ TOP](#)

Manipulation of the Embryo Reveals the Interactions Between its Cells

Confronted with an adult animal, in all its complexity, how does one begin to analyze the process that brought it into being? The first essential step is to describe the anatomical changes—the patterns of cell division, growth, and movement—that convert the egg into the mature organism. This is the job of *descriptive embryology*, and it is harder than one might think. To explain development in terms of cell behavior, we need to be able to track the individual cells through all their divisions, transformations, and migrations in the embryo. The foundations of descriptive embryology were laid in the 19th century, but the fine-grained task of *cell lineage tracing* continues to tax the ingenuity of developmental biologists ([Figure 21-5](#))

Given a description, how can one go on to discover the causal mechanisms? Traditionally, *experimental embryologists* have tried to understand development in terms of the ways in which cells and tissues interact to generate the multicellular structure. *Developmental geneticists*, meanwhile, have tried to analyze development in terms of the actions of genes. These two approaches are complementary, and they have converged to produce our present understanding.

In experimental embryology, cells and tissues from developing animals are removed, rearranged, transplanted, or grown in isolation, in order to discover how they influence one another. The results are often startling: an early embryo cut in half, for example, may yield two complete and perfectly formed animals or a small piece of tissue transplanted to a new site may reorganize the whole structure of the developing body ([Figure 21-6](#)). Observations of this type can be extended and refined to decipher the underlying cell-cell interactions and rules of cell behavior. The experiments are easiest to perform in large embryos that are readily accessible for microsurgery. Thus, the most widely used species have been birds—especially the chick—and amphibians—particularly the African frog *Xenopus laevis*. [↑ TOP](#)

Studies of Mutant Animals Identify the Genes That Control Developmental Processes

Developmental genetics begins with the isolation of mutant animals whose development is abnormal. This typically involves a *genetic screen*, as described in [Chapter 8](#). Parent animals are treated with a chemical mutagen or ionizing radiation to induce mutations in their germ cells, and large numbers of their progeny are examined. Those rare mutant individuals that show some interesting developmental abnormality—altered development of the eye, for example—are picked out for further study. In this way, it is possible to discover genes that are required specifically for the normal development of any

chosen feature. By cloning and sequencing a gene found in this way, it is possible to identify its protein product, to investigate how it works, and to begin an analysis of the regulatory DNA that controls its expression.

The genetic approach is easiest in small animals with short generation times that can be grown in the laboratory. The first animal to be studied in this way was the fruit fly *Drosophila melanogaster*, which will be discussed at length below. But the same approach has been successful in the nematode worm, *Caenorhabditis elegans*, the zebrafish, *Danio rerio*, and the mouse, *Mus musculus*. Although humans are not intentionally mutagenized, they get screened for abnormalities in enormous numbers through the medical care system. Many mutations have arisen in humans that cause abnormalities compatible with life, and analyses of the affected individuals and of their cells have provided important insights into developmental processes. [↑ TOP](#)

A Cell Makes Developmental Decisions Long Before It Shows a Visible Change

By simply watching closely, or with the help of tracer dyes and other cell-marking techniques, one can discover what the fate of a given cell in an embryo will be if that embryo is left to develop normally. The cell may be fated to die, for example, or to become a neuron, to form part of an organ such as the foot, or to give progeny cells scattered all over the body. To know the cell fate, in this sense, however, is to know next to nothing about the cell's intrinsic character. At one extreme, the cell that is fated to become, say, a neuron may be already specialized in a way that guarantees that it will become a neuron no matter how its surroundings are disturbed; such a cell is said to be determined for its fate. At the opposite extreme, the cell may be biochemically identical to other cells destined for other fates, the only difference between them being the accident of position, which exposes the cells to different future influences.

A cell's state of determination can be tested by transplanting it to altered environments ([Figure 21-7](#)). One of the key conclusions of experimental embryology has been that, thanks to cell memory, a cell can become determined long before it shows any obvious outward sign of differentiation.

Between the extremes of the fully determined and the completely undetermined cell, there is a whole spectrum of possibilities. A cell may, for example, be already somewhat specialized for its normal fate, with a strong tendency to develop in that direction, but still able to change and undergo a different fate if it is put in a sufficiently coercive environment. (Some developmental biologists would describe such a cell as *specified* or *committed*, but not yet determined.) Or the cell may be determined, say, as a brain cell, but not yet determined as to whether it is to be a neuronal or a glial component of the brain. And often, it seems, adjacent cells of the same type interact and depend on mutual support to maintain their specialized character, so that they

will behave as determined if kept together in a cluster, but not if taken singly and isolated from their usual companions. [↑ TOP](#)

Cells Have Remembered Positional Values That Reflect Their Location in the Body

In many systems, long before cells become committed to differentiating as a specific cell type, they become *regionally determined*: that is, they switch on and maintain expression of genes that can best be regarded as markers of position or region in the body. This position-specific character of a cell is called its **positional value**, and it shows its effects in the way the cell behaves in subsequent steps of pattern formation.

The development of the chick leg and wing provides a striking example. The leg and the wing of the adult both consist of muscle, bone, skin, and so on—almost exactly the same range of differentiated tissues. The difference between the two limbs lies not in the types of tissues, but in the way in which those tissues are arranged in space. So how does the difference come about?

In the chick embryo the leg and the wing originate at about the same time in the form of small tongue-shaped buds projecting from the flank. The cells in the two pairs of limb buds appear similar and uniformly undifferentiated at first. But a simple experiment shows that this appearance of similarity is deceptive. A small block of undifferentiated tissue at the base of the leg bud, from the region that would normally give rise to part of the thigh, can be cut out and grafted into the tip of the wing bud. Remarkably, the graft forms not the appropriate part of the wing tip, nor a misplaced piece of thigh tissue, but a toe ([Figure 21-8](#)). This experiment shows that the early leg-bud cells are already determined as leg but are not yet irrevocably committed to form a particular part of the leg: they can still respond to cues in the wing bud so that they form structures appropriate to the tip of the limb rather than the base. The signaling system that controls the differences between the parts of the limb is apparently the same for leg and wing. The difference between the two limbs results from a difference in the internal states of their cells at the outset of limb development.

The difference of positional value between vertebrate forelimb cells and hindlimb cells appears to be a reflection of differential expression of a class of gene regulatory proteins called T-box (Tbx) proteins. The cells of the hindlimb bud express the *Tbx4* gene while those of the forelimb bud express *Tbx5*, and this is thought to control their subsequent behavior ([Figure 21-9](#)). Later in this chapter we shall explain how the next, more detailed level of patterning is set up inside an individual limb bud. [↑ TOP](#)

Sister Cells Can Be Born Different by an Asymmetric Cell Division

At each stage in its development, a cell in an embryo is presented with a limited set of options according to the state it has attained: the cell travels along a developmental pathway that branches repeatedly. At each branch in the pathway it has to make a choice, and its sequence of choices determines its final destiny. In this way, a complicated array of different cell types is produced.

To understand development, we need to know how each choice between options is controlled, and how those options depend on the choices made previously. To reduce the question to its simplest form: how do two cells with the same genome come to be different?

When a cell undergoes mitosis, both of the resulting daughter cells receive a precise copy of the mother cell's genome. Yet those daughters will often have different specialized fates, and, at some point, they or their progeny must acquire different characters.

In some cases, the two sister cells are born different as a result of an asymmetric cell division, in which some significant set of molecules is divided unequally between the two daughter cells at the time of division. This asymmetrically segregated molecule (or set of molecules) then acts as a *determinant* for one of the cell fates by directly or indirectly altering the pattern of gene expression within the daughter cell that receives it (Figure 21-10).

Asymmetric divisions are particularly common at the beginning of development, when the fertilized egg divides to give daughter cells with different fates, but they also occur at later stages—in the genesis of nerve cells, for example.  [TOP](#)

Inductive Interactions Can Create Orderly Differences Between Initially Identical Cells

An alternative and by far the commonest way to make cells different is by exposing them to different environments, and the most important environmental cues acting on cells in an embryo are signals from neighboring cells.

In some cases, adjacent initially similar cells exchange signals that drive them to become different from one another, as in a competition between identical twins. A sort of shouting match occurs, from which one cell or group of cells emerges as winner—not only specializing in a particular way but also delivering a signal to neighboring cells that inhibits them from doing likewise—a phenomenon called *lateral inhibition* (Figure 21-11). Very often, this process is based on an exchange of signals at cell-cell contacts via the Notch pathway (discussed in Chapter 15).

In another strategy, perhaps the widely used of all, a group of cells start out all having the same developmental potential, and a signal from cells outside the group then drives one or more of the members of the group into a different developmental pathway, leading to a changed character. This process is called an **inductive interaction**. Generally, the signal is limited in time and space so that only a subset of the competent cells—those closest to the source of the signal—take on the induced character ([Figure 21-12](#)).

Some inductive signals are short-range—notably those transmitted via cell-cell contacts; others are long-range, mediated by molecules that can diffuse through the extracellular medium. The group of initially similar cells competent to respond to the signal is sometimes called an *equivalence group* or a *morphogenetic field*. It can consist of as few as two cells or as many as thousands, and any number of the total can be induced depending on the amount and distribution of the signal.

In principle, any kind of signal molecule could serve as an inducer. In practice, most of the known inductive events in animal development are governed by just a handful of highly conserved families of signal proteins, which are used over and over again in different contexts. The discovery of this limited vocabulary that cells use for developmental communications has emerged over the last ten or twenty years as one of the great simplifying discoveries of developmental biology. In [Table 21-1](#), we briefly review five major families of signal proteins that serve repeatedly as inducers in animal development. Details of the intracellular mechanisms through which these molecules act are given in [Chapter 15](#).

The ultimate result of most inductive events is a change in DNA transcription in the responding cell: some genes are turned on and others are turned off. Different signaling molecules activate different kinds of gene regulatory proteins. Moreover, the effect of activating a given gene regulatory protein will depend on which other gene regulatory proteins are also present in the cell, since these generally function in combinations. As a result, different types of cells will generally respond differently to the same signal. The response will depend both on the other gene regulatory proteins that are present before the signal arrives—reflecting the cell's memory of signals received previously—and on the other signals that the cell is receiving at the same time. [↑ TOP](#)

Morphogens Are Long-Range Inducers That Exert Graded Effects

So far, we have spoken of signal molecules as though they governed a simple yes-no choice: one effect in their presence, another in their absence. In many cases, however, responses are more finely graded: a high concentration may, for example, direct target cells into one developmental pathway, an

intermediate concentration into another, and a low concentration into yet another. An important case is that in which the signaling molecule diffuses out from a localized source, creating a signal concentration gradient. Cells at different distances from the source are driven to behave in a variety of different ways, according to the signal concentration that they experience.

A signaling molecule that imposes a pattern on a whole field of cells in this way is called a morphogen. Vertebrate limbs provide a striking example: a specialized group of cells at one side of the embryonic limb bud secrete Sonic hedgehog protein—a member of the Hedgehog family of signal molecules—and this protein spreads out from its source, forming a *morphogen gradient* that controls the characters of the cells along the thumb-to-little-finger axis of the limb bud. If an additional group of signaling cells is grafted into the opposite side of the bud, a mirror duplication of the pattern of digits is produced ([Figure 21-13](#)). [↑ TOP](#)

Extracellular Inhibitors of Signal Molecules Shape the Response to the Inducer

Especially for molecules that can act at a distance, it is important to limit the action of the signal, as well as to produce it. Most developmental signal proteins have extracellular antagonists that can inhibit their function. These antagonists are generally proteins that bind to the signal or its receptor, preventing a productive interaction from taking place.

A surprisingly large number of developmental decisions are actually regulated by inhibitors rather than by the primary signal molecule. The nervous system in a frog embryo arises from a field of cells that is competent to form either neural or epidermal tissue. An inducing tissue releases the protein chordin, which favors the formation of neural tissue. Chordin does not have its own receptor. Instead it is an inhibitor of signal proteins of the BMP/TGF β family, which induce epidermal development and are present throughout the neuroepithelial region where neurons and epidermis form. The induction of neural tissue is thus due to an inhibitory gradient of an antagonistic signal ([Figure 21-14](#)). [↑ TOP](#)

Programs That Are Intrinsic to a Cell Often Define the Time-Course of its Development

Signals such as those we have just discussed play a large part in controlling the timing of events in development, but it would be wrong to imagine that every developmental change needs an inductive signal to trigger it. Many of the mechanisms that alter cell character are intrinsic to the cell and require no cue from the cell's surroundings: the cell will step through its developmental program even when kept in a constant environment. There are numerous cases where one might suspect that something of this sort is occurring to control the

duration of a developmental process. For example, in a mouse, the neural progenitor cells in the cerebral cortex of the brain carry on dividing and generating neurons for just 11 cell cycles, and in a monkey for approximately 28 cycles, after which they stop. Moreover, different kinds of neurons are generated at different stages in this program, suggesting that as the progenitor cell ages, it changes the specifications that it supplies to the differentiating progeny cells.

It is difficult to prove in the context of the intact embryo that such a course of events is strictly the result of a cell-autonomous timekeeping process, since the cell environment is changing. Experiments on cells in culture, however, give clear-cut evidence. For example, glial progenitor cells isolated from the optic nerve of a 7-day postnatal rat and cultured under constant conditions in an appropriate medium will carry on proliferating for a strictly limited time (corresponding to a maximum of about eight cell division cycles) and then differentiate into oligodendrocytes (the glial cells that form myelin sheaths around axons in the brain), obeying a timetable similar to the one that they would have followed if they had been left in place in the embryo. [↑ TOP](#)

Initial Patterns Are Established in Small Fields of Cells and Refined by Sequential Induction as the Embryo Grows

The signals that organize the spatial pattern of an embryo generally act over short distances and govern relatively simple choices. A morphogen, for example, typically acts over a distance of less than 1 mm—an effective range for diffusion—and directs choices between no more than a handful of developmental options for the cells on which it acts. But the organs that eventually develop are much larger and more complex than this.

The cell proliferation that follows the initial specification accounts for the size increase, while the refinement of the initial pattern is explained by a series of local inductions that embroider successive levels of detail on an initially simple sketch. As soon as two sorts of cells are present, one of them can produce a factor that induces a subset of the neighboring cells to specialize in a third way. The third cell type can in turn signal back to the other two cell types nearby, generating a fourth and a fifth cell type, and so on ([Figure 21-15](#)).

This strategy for generating a progressively more complicated pattern is called **sequential induction**. It is chiefly through sequential inductions that the body plan of a developing animal, after being first roughed out in miniature, becomes elaborated with finer and finer details as development proceeds.

In the sections that follow, we focus on a small selection of model organisms to see how the principles that we have outlined in this first section operate in practice. We begin with the nematode worm, *Caenorhabditis elegans*. [↑ TOP](#)

Summary

The obvious changes of cell behavior that we see as a multicellular organism develops are the outward signs of a complex molecular computation, dependent on cell memory, that is taking place inside the cells as they receive and process signals from their neighbours and emit signals in return. The final pattern of differentiated cell types is thus the outcome of a more hidden program of cell specialization—a program played out in the changing patterns of expression of gene regulatory proteins, giving one cell different potentialities from another long before terminal differentiation begins. Developmental biologists seek to decipher the hidden program and to relate it, through genetic and microsurgical experiments, to the signals the cells exchange as they proliferate, interact, and move.

Animals as different as worms, flies, and humans use remarkably similar sets of proteins to control their development, so that what we discover in one organism very often gives insight into the others. A handful of evolutionarily conserved cell-cell signaling pathways are used repeatedly, in different organisms and at different times, to regulate the creation of an organized multicellular pattern. Differences of body plan seem to arise to a large extent from differences in the regulatory DNA associated with each gene. This DNA has a central role in defining the sequential program of development, calling genes into action at specific times and places according to the pattern of gene expression that was present in each cell at the previous developmental stage.

Differences between cells in an embryo arise in various ways. Sister cells can be born different, as a result of an asymmetric cell division. Alternatively, cells that are born similar can become different through a competitive interaction with one another, as in lateral inhibition. Or a group of initially similar cells may receive different exposures to inductive signals from cells outside the group; long-range inducers with graded effects, called morphogens, can organize a complex pattern. Through cell memory, such transient signals can have a lasting effect on the internal state of a cell, causing it, for example, to become determined for specific fate. In these ways, sequences of simple signals acting at different times and places in growing cell arrays give rise to the intricate and varied multicellular organisms that fill the world around us. Figure 21-2. Homologous proteins functioning interchangeably in the development of mice and flies. (A) A fly protein used in a mouse. The DNA sequence from *Drosophila* coding for the Engrailed protein (a gene regulatory protein) can be substituted for the corresponding sequence coding for the Engrailed-1 protein of the mouse. Loss of Engrailed-1 in the mouse causes a defect in its brain (the cerebellum fails to develop); the *Drosophila* protein acts as an efficient substitute, rescuing the transgenic mouse from this deformity. (B) A mollusc protein used in a fly. The Eyeless protein controls eye development in *Drosophila*, and when misexpressed can cause an eye to develop in an abnormal site, such as a leg. The homologous protein, Pax-6, from a mouse, a squid, or practically any animal possessing eyes, when similarly misexpressed in a transgenic fly, has the same effect. The scanning electron micrographs show a patch of eye tissue on the leg of a fly resulting from misexpression of *Drosophila* Eyeless (*above*) and of squid Pax-6 (*below*). (A, from M.C. Figure 21-11. Lateral inhibition and cell diversification. Adjacent cells compete to adopt the primary character (*blue*), by delivering inhibitory signals to one another. At first, all cells in the patch are similar. Any cell that gains an advantage in the competition (*darker blue*) delivers a stronger inhibitory signal (more *red* inhibition signals) to its neighbors, inhibiting them from delivering inhibitory signals themselves in return. This effect is self-reinforcing, and it leads to creation of a fine-grained mixture in which the cells finally adopting the primary character (*deep blue*) are surrounded by inhibited cells that adopt a different character (*gray*).

Table 21-1. Some Signal Proteins That Are Used Over and Over Again as Inducers in Animal Development

SIGNALING PATHWAY	LIGAND FAMILY	RECEPTOR FAMILY	EXTRACELLULAR INHIBITORS/MODULATORS
Receptor tyrosine kinase (RTK)	EGF	EGF receptors	Argos
	FGF (Branchless)	FGF receptors (Breathless)	
	ephrins	Eph receptors	
TGF β superfamily	TGF β	TGF β receptors	chordin (Sog), noggin
	BMP (Dpp)	BMP receptors	
	Nodal		
Wnt	Wnt (Wingless)	Frizzled	Dickkopf, Cerberus
Hedgehog	Hedgehog	Patched, Smoothed	
Notch	Delta	Notch	Fringe

Only a few representatives of each class of proteins are listed—mainly those mentioned in this chapter. Names peculiar to *Drosophila* are shown in parentheses. Many of the listed components have several homologs distinguished by numbers (FGF1, FGF2, etc.) or by forenames (Sonic hedgehog, Lunatic fringe). For further details, see [Chapter 15](#).

Development of Multicellular Organisms

Caenorhabditis Elegans: Development from the Perspective of the Individual Cell

The nematode worm *Caenorhabditis elegans* is a small, relatively simple, and precisely structured organism. The anatomy of its development has been described in extraordinary detail, and one can map out the exact lineage of every cell in the body. Its complete genome sequence is also known, and large numbers of mutant phenotypes have been analyzed to determine gene functions. If there is any multicellular animal whose development we should be able to understand in terms of genetic control, this is it.

There are, it is true, some factors that make such an understanding difficult. Anatomically simple though it is, it has more genes (about 18,000) and more cells (about 1000) than one can easily keep track of without a computer. It is not the most directly instructive model organism if one wants to understand how animals such as ourselves form organs such as eyes or limbs, which the worm lacks, and it is hard to do transplantation experiments. Moreover, DNA sequence comparisons indicate that, while the lineages leading to nematodes, insects, and vertebrates diverged from one another at about the same time, the rate of evolutionary change in the nematode lineage has been substantially greater: both its genes and its body structure are more divergent from our own than are those of *Drosophila*.

In spite of all this, the worm presents us with an excellent introductory example: it poses the basic general questions of animal development in a relatively simple form, and it lets us answer them in terms of the behavior of individual, identified cells.

Caenorhabditis elegans Is Anatomically Simple

As an adult, *C. elegans* consists of only about 1000 somatic cells and 1000–2000 germ cells (exactly 959 somatic cell nuclei plus about 2000 germ cells are counted in one sex; exactly 1031 somatic cell nuclei plus about 1000 germ cells in the other) (Figure 21-16). The anatomy has been reconstructed, cell by cell, by electron microscopy of serial sections. The body plan of the worm is simple: it has a roughly bilaterally symmetrical, elongate body

composed of the same basic tissues as in other animals (nerve, muscle, gut, skin), organized with mouth and brain at the anterior end and anus at the posterior. The outer body wall is composed of two layers: the protective epidermis, or "skin," and the underlying muscular layer. A tube of endodermal cells forms the intestine. A second tube, located between the intestine and the body wall, constitutes the gonad; its wall is composed of somatic cells, with the germ cells inside it.

C. elegans has two sexes—a hermaphrodite and a male. The hermaphrodite can be viewed most simply as a female that produces a limited number of sperm: she can reproduce either by self-fertilization, using her own sperm, or by cross-fertilization after transfer of male sperm by mating. Self-fertilization allows a single heterozygous worm to produce homozygous progeny. This is an important feature that helps to make *C. elegans* an exceptionally convenient organism for genetic studies. [↑ TOP](#)

Cell Fates in the Developing Nematode Are Almost Perfectly Predictable

C. elegans begins life as a single cell, the fertilized egg, which gives rise, through repeated cell divisions, to 558 cells that form a small worm inside the egg shell. After hatching, further divisions result in the growth and sexual maturation of the worm as it passes through four successive larval stages separated by molts. After the final molt to the adult stage, the hermaphrodite worm begins to produce its own eggs. The entire developmental sequence, from egg to egg, takes only about three days.

The lineage of all of the cells from the single-cell egg to the multicellular adult was mapped out by direct observation of the developing animal. In the nematode, a given precursor cell follows the same pattern of cell divisions in every individual, and with very few exceptions the fate of each descendant cell can be predicted from its position in the lineage tree ([Figure 21-17](#)).

This degree of stereotyped precision is not seen in the development of larger animals. At first sight, it might seem to suggest that each cell lineage in the nematode embryo is rigidly and independently programmed to follow a set pattern of cell division and cell specialization, making the worm a woefully unrepresentative model organism for development. We shall see that this is far from true: as in other animals, development depends on cell-cell interactions as well as on processes internal to the individual cells. The outcome in the nematode is almost perfectly predictable simply because the pattern of cell-cell interactions is highly reproducible and is accurately correlated with the sequence of cell divisions. [↑ TOP](#)

Products of Maternal-Effect Genes Organize the Asymmetric Division of the Egg

Search

This book
books

All

PubMed

In the developing worm, as in other animals, most cells do not become restricted to a single pathway of differentiation until quite late in development, and cells of a particular type, such as muscle, usually derive from several spatially dispersed precursors that also give rise to other types of cells. The exceptions, in the worm, are the gut and the gonad, each of which forms from a single dedicated *founder cell*, born at the 8-cell stage of development for the gut-cell lineage and at the 16-cell stage for the germ-cell lineage, or *germ line*. Other cells in the embryo, meanwhile, are also becoming different from one another, even though they are not yet committed with regard to their terminal mode of differentiation. How do these early differences between cells arise?

The worm is typical of most animals in the early specification of the cells that will eventually give rise to the germ cells (eggs or sperm). The worm's germ line is produced by a strict series of asymmetric cell divisions of the fertilized egg. The asymmetry originates with a cue from the egg's environment: the sperm entry point defines the future posterior pole of the elongated egg. The proteins in the egg then interact with one another and organize themselves in relation to this point so as to create a more elaborate and extreme asymmetry in the interior of the cell. The proteins involved are mainly translated from the accumulated mRNA products of the genes of the mother. Because this RNA is made before the egg is laid, it is only the mother's genotype that dictates what happens in the first steps of development. Genes acting in this way are called **maternal-effect genes**.

A subset of maternal-effect genes are specifically required to organize the asymmetric pattern of the nematode egg. These are called *par* (*partitioning-defective*) genes, and at least six have been identified, through genetic screens for mutants where this pattern is disrupted. The *par* genes have homologs in insects and vertebrates, where they are also involved in organizing cell asymmetry, coordinating the polarization of the cytoskeleton with the distribution of other cell components

In the nematode egg, the Par proteins (the products of the *par* genes) serve to bring a set of ribonucleoprotein particles called *P granules* to the posterior pole, so that the posterior daughter cell inherits P granules and the anterior daughter cell does not. Throughout the next few cell divisions, the Par proteins operate in a similar way, orienting the mitotic spindle and segregating the P granules to one daughter cell at each mitosis, until, at the 16-cell stage, there is just one cell that contains the P granules (Figure 21-18). This one cell gives rise to the germ line.

The specification of the germ-cell precursors as distinct from somatic-cell precursors is a key event in the development of practically every type of animal, and the process has common features even in phyla with very different body plans. Thus in *Drosophila*, particles similar to P granules are also segregated into one end of the egg, and become incorporated into the germ-line precursor cells to determine their fate. Similar phenomena occur in fish and frogs. In all these species, one can recognise at least some of the same proteins

in the germ-cell-determining material, including homologs of an RNA-binding protein called Vasa. How Vasa and its associated proteins and RNA molecules act to define the germ line is still unknown. [↑ TOP](#)

Progressively More Complex Patterns Are Created by Cell-Cell Interactions

The egg, in *C. elegans* as in other animals, is an unusually big cell, with room for complex internal patterning. In addition to the P granules, other factors become distributed in an orderly way along its anteroposterior axis under the control of the Par proteins, and thus are allocated to different cells as the egg goes through its first few cell-division cycles. These divisions occur without growth (since feeding cannot begin until a mouth and a gut have formed) and therefore subdivide the egg into progressively smaller cells. Several of the localized factors are gene regulatory proteins, which act directly in the cell that inherits them to either drive or block the expression of specific genes, adding to the differences between that cell and its neighbors and committing it to a specialized fate.

While the first few differences between cells along the anteroposterior axis of *C. elegans* result from asymmetric divisions, further patterning, including the pattern of cell types along the other axes, depends on interactions between one cell and another. The cell lineages in the embryo are so reproducible that individual cells can be assigned names and identified in every animal ([Figure 21-19](#)); the cells at the four-cell stage, for example, are called ABa and ABp (the two anterior sister cells), and EMS and P₂ (the two posterior sister cells).

As a result of the asymmetric divisions we have just described, the P₂ cell expresses a signal protein on its surface—a nematode homolog of the Notch ligand Delta—while the ABa and ABp cells express the corresponding transmembrane receptor—a homolog of Notch. The elongated shape of the eggshell forces these cells into an arrangement such that the most anterior cell, ABa, and the most posterior cell, P₂, are no longer in contact with one another.

Thus only the ABp cell and the EMS cell are exposed to the signal from P₂.

This signal acts on ABp, making it different from ABa and defining the future dorsal-ventral axis of the worm ([Figure 21-20](#)).

At the same time, P₂ also expresses another signaling molecule, a Wnt protein, which acts on a Wnt receptor (a Frizzled protein) in the membrane of the EMS cell. This signal polarizes the EMS cell in relation to its site of contact with P₂, controlling the orientation of the mitotic spindle. The EMS cell then divides to give two daughters that become committed to different fates as a result of the Wnt signal from P₂. One daughter, the MS cell, will give rise to muscles and various other body parts; the other daughter, the E cell, is the founder cell for the gut, committed to give rise to all the cells of the gut and to no other tissues

(see [Figure 21-20](#)).

Having described the chain of cause and effect in early nematode development, we now examine some of the methods that have been used to decipher it. [↑ TOP](#)

Microsurgery and Genetics Reveal the Logic of Developmental Control; Gene Cloning and Sequencing Reveal Its Molecular Mechanisms

To discover the causal mechanisms, we need to know the developmental potential of the individual cells in the embryo. At what points in their lives do they undergo decisive internal changes that determine them for a particular fate, and at what points do they depend on signals from other cells? In the nematode, laser microbeam microsurgery can be conveniently used to kill one or more of a cell's neighbors and then to observe directly how the cell behaves in the altered circumstances. Alternatively, cells of the early embryo can be pushed around and rearranged inside the eggshell using a fine needle. For example, the relative positions of ABa and ABp can be flipped at the four-cell stage of development. The ABa cell then undergoes what would normally be the fate of the ABp cell, and vice versa, showing that the two cells initially have the same developmental potential and depend on signals from their neighbors to make them different. A third tactic is to remove the eggshell of an early *C. elegans* embryo by digesting it with enzymes, and then to manipulate the cells in culture. The existence of a polarizing signal from P₂ to EMS was demonstrated in this way.

Genetic screens were used to identify the genes involved in the P₂-EMS cell interaction. A search was made for mutant strains of worms in which no gut cells were induced (called *mom* mutants, because they had *more* mesoderm—mesoderm being the fate of both of the EMS cell daughters when induction fails). Cloning and sequencing the *mom* genes revealed that one encodes a Wnt signal protein that is expressed in the P₂ cell, while another encodes a Frizzled protein (a Wnt receptor) that is expressed in the EMS cell. A second genetic screen was conducted for mutant strains of worms with the opposite phenotype, in which extra gut cells are induced (called *pop* mutants, because they have *plenty of pharynx* as a result of the extra gut). One of the *pop* genes (*pop-1*) turns out to encode a gene regulatory protein (a LEF-1/TCF homolog) whose activity is down-regulated by Wnt signaling in *C. elegans*. When Pop-1 activity is absent, both daughters of the EMS cell behave as though they have received the Wnt signal from P₂. Similar genetic methods were used to identify the genes whose products mediate the Notch-dependent signaling from P₂ to ABa.

Continuing in this way, it is possible to build up a detailed picture of the

decisive events in nematode development, and of the genetically specified machinery that controls them. [↑ TOP](#)

Cells Change Over Time in Their Responsiveness to Developmental Signals

The complexity of the adult nematode body is achieved through repeated use of a handful of patterning mechanisms, including those we have just seen in action in the early embryo. For example, asymmetric cell divisions dependent on the Pop-1 gene regulatory proteins occur throughout *C. elegans* development, creating differences between anterior and posterior sister cells.

As emphasized earlier, while the same few types of signals act repeatedly at different times and places, the effects they have are different because the cells are programmed to respond differently according to their age and their past history. We have seen, for example, that at the four-cell stage of development, one cell, ABp, changes its developmental potential because of a signal received via the Notch pathway. At the 12-cell stage of development, the granddaughters of the ABp cell and the granddaughters of the ABa cell both encounter another Notch signal, this time from a daughter of the EMS cell. The ABa granddaughter changes its internal state in response to this signal and begins to form the pharynx. The ABp granddaughter does no such thing—the earlier exposure to a Notch signal has made it unresponsive. Thus, at different times in their history, both ABa lineage cells and ABp lineage cells respond to Notch, but the outcomes are different. Somehow a Notch signal at the 12-cell stage induces pharynx, but a Notch signal at the 4-cell stage has other effects—which include the prevention of pharynx induction by Notch at a later stage. [↑ TOP](#)

Heterochronic Genes Control the Timing of Development

A cell does not have to receive an external cue in order to change: one set of regulatory molecules inside the cell can provoke production of another, and the cell can thus step through a series of different states autonomously. These states differ not only in their responsiveness to external signals, but also in other aspects of their internal chemistry, including proteins that stop or start the cell-division cycle. In this way, the internal mechanisms of the cell, together with the past and present signals received, dictate both the sequence of biochemical changes in the cell and the timing of its cell divisions.

The specific molecular details of the mechanisms governing the temporal program of development are still mysterious. Remarkably little is known, even in the nematode embryo with its rigidly predictable pattern of cell divisions, about how the sequence of cell divisions is controlled. However, for the later stages, when the larva feeds and grows and moults to become an adult, it has been possible to identify some of the genes that control the timing of cellular events. Mutations in these genes cause *heterochronic* phenotypes: the cells in a

larva of one stage behave as though they belonged to a larva of a different stage, or cells in the adult carry on dividing as though they belonged to a larva (Figure 21-21).

Through genetic analyses, one can determine that the products of the heterochronic genes act in series, forming regulatory cascades. Curiously, two genes at the top of their respective cascades, called *lin-4* and *let-7*, do not code for proteins but for short untranslated RNA molecules (21 or 22 nucleotides long). These act by binding to complementary sequences in the non-coding regions of mRNA molecules transcribed from other heterochronic genes, thereby controlling their rate of translation or possibly their degradation (perhaps by a mechanism similar to that of RNAi—see p. 451). Increasing levels of *lin-4* RNA govern the progression from larval stage-1 cell behavior to larval stage-3 cell behavior, increasing levels of *let-7* RNA govern the progression from late larva to adult.

RNA molecules that are identical or almost identical to the *let-7* RNA are found in many other species, including *Drosophila*, zebrafish, and human. Moreover, these RNAs appear to act in a similar way to regulate the level of their target mRNA molecules, and the targets themselves are homologous to the targets of *let-7* RNA in the nematode. The evidence therefore suggests that this system has a universal role in governing the timing of a switch from an early to a late style of cell behavior. [↑ TOP](#)

Cells Do Not Count Cell Divisions in Timing Their Internal Programs

Since the steps of cell specialization have to be coordinated with cell divisions, it is often suggested that the cell division cycle might serve as a clock to control the tempo of other events in development. In this view, changes of internal state would be locked to passage through each division cycle: the cell would click to the next state as it went through mitosis, so to speak. There is a substantial amount of evidence that this idea is wrong. Cells in developing embryos, whether they be worms, flies, or vertebrates, usually carry on with their standard timetable of determination and differentiation even when progress through the cell-division cycle is artificially blocked. Necessarily, there are some abnormalities, if only because a single undivided cell cannot differentiate in two ways at once. But in most cases that have been studied, it seems clear that the cell changes its state with time regardless of cell division, and that this changing state controls both the decision to divide and the decision as to when and how to specialize. [↑ TOP](#)

Selected Cells Die by Apoptosis as Part of the Program of Development

The control of cell numbers in development depends on cell death as well as

cell division. A *C. elegans* hermaphrodite generates 1030 somatic cell nuclei in the course of its development, but 131 of the cells die. These programmed cell deaths occur in an absolutely predictable pattern. In *C. elegans*, they can be chronicled in detail, because one can trace the fate of each individual cell and see who dies, watching as each suicide victim undergoes apoptosis and is rapidly engulfed and digested by neighboring cells (Figure 21-22). In other organisms, where close observation is harder, such deaths easily go unnoticed; but cell death by apoptosis is probably the fate of a substantial fraction of the cells produced in most animals, playing an essential part in generating an individual with the right cell types in the right numbers and places, as discussed in [Chapter 17](#).

Genetic screens in *C. elegans* have been crucial in identifying the genes that bring about apoptosis and in highlighting its importance in development. Three genes, called *ced-3*, *ced-4*, and *egl-1*, (*ced* stands for *cell death abnormal*), are found to be required for the 131 normal cell deaths to occur. If these genes are inactivated by mutation, cells that are normally fated to die survive instead, differentiating as recognizable cell types such as neurons. Conversely, over-expression or misplaced expression of the same genes causes many cells to die that would normally survive, and the same effect results from mutations that inactivate another gene, *ced-9*, which normally represses the death program.

All these genes code for conserved components of the cell-death machinery. As described in [Chapter 17](#), *ced-3* codes for a caspase homolog, while *ced-4*, *ced-9* and *egl-1* are respectively homologs of *Apaf-1*, *Bcl-2*, and *Bad*. Without the insights that came from detailed analysis of the development of the transparent, genetically tractable nematode worm, it would have been very much harder to discover these genes and understand the cell-death process in vertebrates. [↑ TOP](#)

Summary

The development of the small, relatively simple, transparent nematode worm *Caenorhabditis elegans* is extraordinarily reproducible and has been chronicled in detail, so that a cell at any given position in the body has the same lineage in every individual, and this lineage is fully known. Also, the genome has been completely sequenced. Thus powerful genetic and microsurgical approaches can be combined to decipher developmental mechanisms. As in other organisms, development depends on an interplay of cell-cell interactions and cell-autonomous processes. Development begins with an asymmetric division of the fertilized egg, dividing it into two smaller cells containing different cell-fate determinants. The daughters of these cells interact via the Notch and Wnt cell signaling pathways to create a more diverse array of cell states. Meanwhile, through further asymmetric divisions one cell inherits materials from the egg that determine it at an early stage as progenitor of the germ line.

Genetic screens identify the sets of genes responsible for these and later steps in development, including, for example, cell-death genes that control the apoptosis of a specific subset of cells as part of the normal developmental program. Heterochronic genes that govern the timing of developmental events have also been found, although in general our understanding of temporal control of development is still very poor. There is good evidence, however, that the tempo of development is not set by the counting of cell divisions. [↑ TOP](#)

larva

Figure 21-21. Heterochronic mutations in the *lin-14* gene of *C. elegans*. The effects on only one of the many affected lineages are shown. The loss-of-function (recessive) mutation in *lin-14* causes premature occurrence of the pattern of cell division and differentiation characteristic of a late larva, so that the animal reaches its final state prematurely and with an abnormally small number of cells. The gain-of-function (dominant) mutation has the opposite effect, causing cells to reiterate the patterns of cell divisions characteristic of the first larval stage, continuing through as many as five or six molt cycles and persisting in the manufacture of an immature type of cuticle. The cross denotes a programmed cell death. *Green* lines represent cells that contain Lin-14 protein (which binds to DNA), *red* lines those that do not. In normal development the disappearance of Lin-14 is triggered by the beginning of larval feeding. (After V. Ambros and H.R. Horvitz, *Science* 226:409–416, 1984; P. Arasu, B. Wightman, and G. Ruvkun, *Growth Dev. Aging* 5:1825–1833, 1991.)

Development of Multicellular Organisms

Drosophila and the Molecular Genetics of Pattern Formation: Genesis of the Body Plan

It is the fly *Drosophila melanogaster* (Figure 21-23), more than any other organism, that has transformed our understanding of how genes govern the patterning of the body. The anatomy of *Drosophila* is more complex than that of *C. elegans*, with more than 100 times as many cells, and it shows more obvious parallels with our own body structure. Surprisingly, the fly has fewer genes than the worm—about 14,000 as compared with 19,000. On the other hand, it has almost twice as much noncoding DNA per gene (about 10,000 nucleotides on average, as compared with about 5000). The molecular construction kit has fewer types of parts, but the assembly instructions—as specified by the regulatory sequences in the non-coding DNA—seem to be more voluminous.

Decades of genetic study, culminating in massive systematic genetic screens, have yielded a catalogue of the developmental control genes that define the spatial pattern of cell types and body structures of the fly, and molecular biology has given us the tools to watch these genes in action. By *in situ* hybridization using DNA or RNA probes on whole embryos, or by staining with labeled antibodies to reveal the distribution of specific proteins, one can observe directly how the internal states of the cells are defined by the sets of regulatory genes that they express at different times of development. Moreover, by analyzing animals that are a patchwork of mutant and nonmutant cells, one can discover how each gene operates as part of a system to specify the organization of the body.

Most of the genes controlling the pattern of the body in *Drosophila* turn out to have close counterparts in higher animals, including ourselves. In fact, many of the basic devices for defining the body plan and patterning individual organs and tissues are astonishingly similar. Thus, quite surprisingly, the fly has provided the key to understanding the molecular genetics of our own development.

Flies, like nematode worms, are ideal for genetic studies: cheap to breed, easy to mutagenize, and rapid in their reproductive cycle. But there is a more

fundamental reason why they have been so important for developmental geneticists. As emphasized earlier, as a result of gene duplications, vertebrate genomes often contain two or three homologous genes corresponding to a single gene in the fly. A mutation that disrupts one of these genes very often fails to reveal the gene's core function, because the other homologs share this function and remain active. In the fly, with its more economical gene set, this phenomenon of genetic redundancy is less prevalent. The phenotype of a single mutation in the fly therefore more often directly uncovers the function of the mutant gene.

The Insect Body Is Constructed as a Series of Segmental Units

The timetable of *Drosophila* development, from egg to adult, is summarized in [Figure 21-24](#). The period of *embryonic development* begins at fertilization and takes about a day, at the end of which the embryo hatches out of the egg shell to become a *larva*. The larva then passes through three stages, or *instars*, separated by molts in which it sheds its old coat of cuticle and lays down a larger one. At the end of the third instar it pupates. Inside the *pupa*, a radical remodeling of the body takes place—a process called *metamorphosis*. Eventually, about nine days after fertilization, an adult fly, or *imago*, emerges.

The fly consists of a head, with mouth, eyes, and antennae, followed by three thoracic segments (numbered T1 to T3), and eight or nine abdominal segments (numbered A1 to A9). Each segment, although different from the others, is built according to a similar plan. Segment T1, for example, carries a pair of legs, T2 carries a pair of legs plus a pair of wings, and T3 carries a pair of legs plus a pair of halteres—small knob-shaped balancers important in flight, evolved from the second pair of wings that more primitive insects possess. The quasi-repetitive segmentation develops in the early embryo during the first few hours after fertilization ([Figure 21-25](#)), but it is more obvious in the larva ([Figure 21-26](#)), where the segments look more similar than in the adult. In the embryo it can be seen that the rudiments of the head, or at least the future adult mouth parts, are likewise segmental. At the two ends of the animal, however, there are highly specialized terminal structures that are not segmentally derived.

The boundaries between segments are traditionally defined by visible anatomical markers; but in discussing gene expression patterns it is often convenient to draw a different set of segmental boundaries, defining a series of segmental units called *parasegments*, half a segment out of register with the traditional divisions (see [Figure 21-26](#)). [↑ TOP](#)

Drosophila Begins Its Development as a Syncytium

The egg of *Drosophila* is about 0.5 mm long and 0.15 mm in diameter, with a

[pattern of expression of...](#)

clearly defined polarity. Like the eggs of other insects, but unlike vertebrates, it begins its development in an unusual way: a series of nuclear divisions without cell division creates a syncytium. The early nuclear divisions are synchronous and extremely rapid, occurring about every 8 minutes. The first nine divisions generate a cloud of nuclei, most of which migrate from the middle of the egg toward the surface, where they form a monolayer called the *syncytial blastoderm*. After another four rounds of nuclear division, plasma membranes grow inward from the egg surface to enclose each nucleus, thereby converting the syncytial blastoderm into a *cellular blastoderm* consisting of about 6000 separate cells ([Figure 21-27](#)). About 15 of the nuclei populating the extreme posterior end of the egg are segregated into cells a few cycles earlier; these *pole cells* are the germ-line precursors (primordial germ cells) that will give rise to eggs or sperm.

Up to the cellular blastoderm stage, development depends largely—although not exclusively—on stocks of maternal mRNA and protein that accumulated in the egg before fertilization. The frantic rate of DNA replication and nuclear division evidently gives little opportunity for transcription. After cellularization, cell division continues in a more conventional way, asynchronously and at a slower rate, and the rate of transcription increases dramatically. Gastrulation begins a little while before cellularization is complete, when parts of the sheet of cells forming the exterior of the embryo start to tuck into the interior to form the gut, the musculature, and associated internal tissues. A little later and in another region of the embryo, a separate set of cells move from the surface epithelium into the interior to form the central nervous system. By marking and following the cells through these various movements, one can draw a fate map for the monolayer of cells on the surface of the blastoderm ([Figure 21-28](#)).

As gastrulation nears completion, a series of indentations and bulges appear in the surface of the embryo, marking the subdivision of the body into segments along its anteroposterior axis (see [Figure 21-25](#)). Soon a fully segmented larva emerges, ready to start eating and growing. Within the body of the larva, small groups of cells remain apparently undifferentiated, forming structures called *imaginal discs*. These will grow as the larva grows, and eventually they will give rise to most of the structures of the adult body, as we shall see later.

A head end and a tail end, a ventral (belly) side and a dorsal (back) side, a gut, a nervous system, a series of body segments—these are all features of the basic body plan that *Drosophila* shares with many other animals, including ourselves. We begin our account of the mechanisms of *Drosophila* development by considering how this body plan is set up. [↑ TOP](#)

Genetic Screens Define Groups of Genes Required for Specific Aspects of Early Patterning

By carrying out a series of genetic screens based on saturation mutagenesis

Search

PubMed

(see [Chapter 8](#)), it has been possible to amass a collection of *Drosophila* mutants that appears to include changes in a large proportion of the genes affecting development. Independent mutations in the same gene can be distinguished from mutations in separate genes by a complementation test (see [Panel 8-1](#), p. 527), leading to a catalog of genes classified according to their mutant phenotypes. In such a catalog, a group of genes with very similar mutant phenotypes will often code for a set of proteins that work together to perform a particular function.

Sometimes the developmental functions revealed by mutant phenotypes are those that one would expect; sometimes they are a surprise. A large-scale genetic screen focusing on early *Drosophila* development revealed that the key genes fall into a relatively small set of functional classes defined by their mutant phenotypes. Some—the *egg-polarity genes* ([Figure 21-29](#))—are required to define the anteroposterior and dorsoventral axes of the embryo and mark out its two ends for special fates, by mechanisms involving interactions between the oocyte and surrounding cells in the ovary. Others, the *gap genes*, are required in specific broad regions along the anteroposterior axis of the early embryo to allow their proper development. A third category, the *pair-rule genes*, are required, more surprisingly, for development of alternate body segments. A fourth category, the *segment polarity genes*, are responsible for organizing the anteroposterior pattern of each individual segment.

The discovery of these four systems of genes and the subsequent analysis of their functions (an enterprise that still continues) was a famous tour-de-force of developmental genetics. It has had a revolutionary impact on all of developmental biology by showing the way toward a systematic, comprehensive account of the genetic control of embryonic development. In this section, we shall summarize only briefly the conclusions relating to the earliest phases of *Drosophila* development, because these are insect-specific; we dwell at greater length on the parts of the process that illustrate more general principles. [↑ TOP](#)

Interactions of the Oocyte With Its Surroundings Define the Axes of the Embryo: the Role of the Egg-Polarity Genes

Surprisingly, the earliest steps of animal development are among the most variable, even within a phylum. A frog, a chicken, and a mammal, for example, even though they develop in similar ways later, make eggs that differ radically in size and structure, and they begin their development with different sequences of cell divisions and cell specialization events.

The style of early development that we have described for *C. elegans* is typical of many classes of animals. In contrast, the early development of *Drosophila* represents a rather extreme variant. The main axes of the future insect body are defined before fertilization by a complex exchange of signals between the unfertilized egg, or oocyte, and the follicle cells that surround it in the ovary

(Figure 21-30). Then, in the syncytial phase following fertilization, an exceptional amount of patterning occurs in the array of rapidly dividing nuclei, before the first partitioning of the egg into separate cells. Here, there is no need for the usual forms of cell-cell communication involving transmembrane signaling; neighboring regions of the early *Drosophila* embryo can communicate by means of gene regulatory proteins and mRNA molecules that diffuse or are actively transported through the cytoplasm of the giant multinuclear cell.

In the stages before fertilization, the anteroposterior axis of the future embryo becomes defined by three systems of molecules that create landmarks in the oocyte (Figure 21-31). Following fertilization, each landmark serves as a beacon, providing a signal, in the form of a morphogen gradient, that organizes the developmental process in its neighborhood. Two of these signals are generated from localized deposits of specific mRNA molecules. The future anterior end of the embryo contains a high concentration of mRNA for a gene regulatory protein called Bicoid; this mRNA is translated to produce Bicoid protein, which diffuses away from its source to form a concentration gradient with its maximum at the anterior end of the egg. The future posterior end of the embryo contains a high concentration of mRNA for a regulator of translation called Nanos, which sets up a posterior gradient in the same way. The third signal is generated symmetrically at both ends of the egg, by local activation of a transmembrane tyrosine kinase receptor called Torso. The activated receptor exerts its effects over a shorter range, marking the sites of specialized terminal structures that will form at the head and tail ends of the future larva and also defining the rudiments of the future gut. The three sets of genes responsible for these localized determinants are referred to as the anterior, posterior, and **terminal** sets of **egg-polarity** genes.

A fourth landmark defines the dorsoventral axis (see Figure 21-31): a protein that is produced by follicle cells underneath the future ventral region of the embryo leads to localized activation of another transmembrane receptor, called Toll, in the oocyte membrane. The genes required for this function are called dorsoventral egg-polarity genes.

All the egg-polarity genes in these four classes are maternal-effect genes: it is the mother's genome, not the zygotic genome, that is critical. Thus, a fly whose chromosomes are mutant in both copies of the *bicoid* gene but who is born from a mother carrying one normal copy of *bicoid* develops perfectly normally, without any defects in the head pattern. However, if that daughter fly is a female no functional *bicoid* mRNA can be deposited into the anterior part of her own eggs, and all of these will develop into headless embryos regardless of the father's genotype.

Each of the four egg-polarity signals—provided by Bicoid, Nanos, Torso, and Toll—exerts its effect by regulating (directly or indirectly) the expression of genes in the nuclei of the blastoderm. The use of these particular molecules to

organize the egg is not a general feature of early animal development—indeed, only *Drosophila* and closely related insects possess a *bicoid* gene. And Toll has been coopted here for dorsoventral patterning; its more ancient and universal function is in the innate immune response.

Nevertheless, the egg-polarity system shows some highly conserved features. For example, the localization of *nanos* mRNA at one end of the egg is linked to, and dependent on, the localization of germ-cell determinants at that site, just as it is in *C. elegans*. Later in development, as the zygotic genome comes into play under the influence of the egg-polarity system, more similarities with other animal species become apparent. We shall use the dorsoventral system to illustrate this point.  [TOP](#)

The Dorsoventral Signaling Genes Create a Gradient of a Nuclear Gene Regulatory Protein

Localized activation of the Toll receptor on the ventral side of the egg controls the distribution of Dorsal, a gene regulatory protein inside the egg. The Dorsal protein belongs to the same family as the NF- κ B gene regulatory protein of vertebrates (discussed in [Chapter 15](#)). Its Toll-regulated activity, like that of NF- κ B, depends on its translocation from the cytoplasm, where it is held in an inactive form, to the nucleus, where it regulates gene expression. In the newly laid egg, both the *dorsal* mRNA (detected by *in situ* hybridization) and the protein it encodes (detected with antibodies) are distributed uniformly in the cytoplasm. After the nuclei have migrated to the surface of the embryo to form the blastoderm, however, a remarkable redistribution of the Dorsal protein occurs: dorsally the protein remains in the cytoplasm, but ventrally it is concentrated in the nuclei, with a smooth gradient of nuclear localization between these two extremes ([Figure 21-32](#)). The signal transmitted by the Toll protein controls this redistribution of Dorsal through a signaling pathway that is essentially the same as the Toll-dependent pathway involved in innate immunity.

Once inside the nucleus, the Dorsal protein turns on or off the expression of different sets of genes depending on its concentration. The expression of each responding gene depends on its regulatory DNA—specifically, on the number and affinity of the binding sites that this DNA contains for Dorsal and other regulatory proteins. In this way, the regulatory DNA can be said to *interpret* the positional signal provided by the Dorsal protein gradient, so as to define a dorsoventral series of territories—distinctive bands of cells that run the length of the embryo ([Figure 21-33A](#)). Most ventrally—where the concentration of Dorsal protein is highest—it switches on, for example, the expression of a gene called *twist* that is specific for mesoderm ([Figure 21-34](#)). Most dorsally, where the concentration of Dorsal protein is lowest, the cells switch on *decapentaplegic* (*dpp*). And in an intermediate region, where the concentration of Dorsal protein is high enough to repress *dpp* but too low to activate *twist*, the cells switch on another set of genes, including one called *short gastrulation*

(sog). [↑ TOP](#)

Dpp and Sog Set Up a Secondary Morphogen Gradient to Refine the Pattern of the Dorsal Part of the Embryo

Products of the genes directly regulated by the Dorsal protein generate in turn more local signals that define finer subdivisions of the dorsoventral axis. These signals act after cellularization, and take the form of conventional extracellular signaling molecules. In particular, *dpp* codes for the secreted Dpp protein, which forms a local morphogen gradient in the dorsal part of the embryo. The gene *sog*, meanwhile, codes for another secreted protein that is produced in the neurogenic ectoderm and acts as an antagonist of Dpp. The opposing diffusion gradients of these two proteins create a steep gradient of Dpp activity. The highest Dpp activity levels, in combination with certain other factors, cause development of the most dorsal tissue of all—extraembryonic membrane; intermediate levels cause development of dorsal ectoderm; and very low levels allow development of neurogenic ectoderm ([Figure 21-33B](#)). [↑ TOP](#)

The Insect Dorsoventral Axis Corresponds to the Vertebrate Ventrodorsal Axis

Dpp is a member of the TGF β superfamily of signaling molecules that is also important in vertebrates; Sog is a homolog of the vertebrate protein chordin. It is striking that a Dpp homolog, BMP4, and chordin work together in vertebrates in the same way as do Dpp and Sog in *Drosophila*. These two proteins control the dorsoventral pattern of the ectoderm, with high levels of chordin defining the region that is neurogenic and high levels of BMP4 activity defining the region that is not. This, combined with other molecular parallels, strongly suggests that this part of the body plan, has been conserved between insects and vertebrates. However, the axis is inverted, so that dorsal in the fly corresponds to ventral in the vertebrate ([Figure 21-35](#)). At some point in its evolutionary history, it seems, the ancestor of one of these classes of animals took to living life upside down. [↑ TOP](#)

Three Classes of Segmentation Genes Refine the Anterior-Posterior Maternal Pattern and Subdivide the Embryo

After the initial gradients of Bicoid and Nanos are created to define the anteroposterior axis, the **segmentation genes** refine the pattern. Mutations in any one of the segmentation genes alter the number of segments or their basic internal organization without affecting the global polarity of the embryo. Segmentation genes are expressed by subsets of cells in the embryo, so their products are the first components that the embryo's own genome, rather than the maternal genome, contributes to embryonic development. They are therefore called *zygotic-effect genes* to distinguish them from the earlier maternal-effect genes.

The segmentation genes fall into three groups according to their mutant phenotypes and the stages at which they act ([Figure 21-36](#)). First come a set of at least six **gap genes**, whose products mark out coarse subdivisions of the embryo. Mutations in a gap gene eliminate one or more groups of adjacent segments, and mutations in different gap genes cause different but partially overlapping defects. In the mutant *Krüppel*, for example, the larva lacks eight segments, from T1 to A5 inclusive.

The next segmentation genes to act are a set of eight **pair-rule genes**. Mutations in these cause a series of deletions affecting alternate segments, leaving the embryo with only half as many segments as usual. While all the pair-rule mutants display this two-segment periodicity, they differ in the precise positioning of the deletions relative to the segmental or parasegmental borders. The pair-rule mutant *even-skipped* (*eve*), for example, which is discussed in [Chapter 9](#), lacks the whole of each odd-numbered parasegment, while the pair-rule mutant *fushi tarazu* (*ftz*) lacks the whole of each even-numbered parasegment, and the pair-rule mutant *hairy* lacks a series of regions that are of similar width but out of register with the parasegmental units.

Finally, there are at least 10 **segment-polarity genes**. Mutations in these genes produce larvae with a normal number of segments but with a part of each segment deleted and replaced by a mirror-image duplicate of all or part of the rest of the segment. In *gooseberry* mutants, for example, the posterior half of each segment (that is, the anterior half of each parasegment) is replaced by an approximate mirror image of the adjacent anterior half-segment (see [Figure 21-36](#)).

We see later that, in parallel with the segmentation process, a further set of genes, the *homeotic selector genes*, serve to define and preserve the differences between one segment and the next.

The phenotypes of the various segmentation mutants suggest that the segmentation genes form a coordinated system that subdivides the embryo progressively into smaller and smaller domains along the anteroposterior axis, distinguished by different patterns of gene expression. Molecular genetics has helped to reveal how this system works. [↑ TOP](#)

The Localized Expression of Segmentation Genes Is Regulated by a Hierarchy of Positional Signals

About three-quarters of the segmentation genes, including all of the gap genes and pair-rule genes, code for gene regulatory proteins. Their actions on one another and on other genes can therefore be observed by comparing gene expression in normal and mutant embryos. By using appropriate probes to detect the gene transcripts or their protein products, one can, in effect, take snapshots as genes switch on and off in changing patterns. Repeating the

process with mutants that lack a particular segmentation gene, one can begin to dissect the logic of the entire gene control system.

The products of the egg-polarity genes provide the global positional signals in the early embryo. These cause particular gap genes to be expressed in particular regions. The products of the gap genes then provide a second tier of positional signals that act more locally to regulate finer details of patterning through the expression of yet other genes, including the pair-rule genes ([Figure 21-37](#)). The pair-rule genes in turn collaborate with one another and with the gap genes to set up a regular periodic pattern of expression of segment-polarity genes, and the segment-polarity genes collaborate with one another to define the internal pattern of each individual segment. The strategy, therefore, is one of sequential induction (see [Figure 21-15](#)). By the end of the process, the global gradients produced by the egg-polarity genes have triggered the creation of a fine-grained pattern through a hierarchy of sequential, progressively more local, positional controls. Because the global positional signals that start the process do not have to directly specify fine details, the individual cell nuclei do not have to be governed with extreme precision by small differences in the concentration of these signals. Instead, at each step in the sequence, new signals come into play, providing substantial localized differences of concentration to define new details. Sequential induction is thus a robust strategy. It works reliably to produce fly embryos that all have the same pattern, despite the essential imprecision of biological control systems, and despite variations in conditions such as the temperature at which the fly develops. [↑ TOP](#)

The Modular Nature of Regulatory DNA Allows Genes to Have Multiple Independently Controlled Functions

The elaborate patterning process just described depends on the long stretches of noncoding DNA sequence that control the expression of each of the genes involved. These regulatory regions bind multiple copies of the gene regulatory proteins produced by the patterning genes expressed earlier. Like an input-output logic device, an individual gene is thus turned on and off according to the particular combination of proteins bound to its regulatory regions at each stage of development. In [Chapter 7](#) we describe one particular segmentation gene—the pair-rule gene *even-skipped* (*eve*)—and discuss how the decision whether to transcribe the gene is made on the basis of all these inputs (see [Figure 7-55](#)). This example can be taken further to illustrate some important principles of developmental patterning.

Individual stripes of *eve* expression depend on separate regulatory modules in the *eve* regulatory DNA. Thus, one regulatory module is responsible for driving *eve* expression in stripes 1 + 5, another for stripe 2, another for stripes 3 + 7, and yet another for stripes 4 + 6 ([Figure 21-38](#)). Each regulatory module defines a different set of requirements for gene expression according to the concentrations of the products of the egg-polarity and gap genes. In this

way, the *eve* regulatory DNA serves to translate the complex nonrepetitive pattern of egg-polarity and gap proteins into the periodic pattern of expression of a pair-rule gene.

The modular organization of the *eve* regulatory DNA just described is typical of gene regulation in multicellular animals and plants, and it has profound implications. By stringing together sequences of modules that respond to different combinations of regulatory proteins, it is possible to generate almost any pattern of gene expression on the basis of almost any other. Modularity, moreover, allows the regulatory DNA to define patterns of gene expression that are not merely complex, but whose parts are independently adjustable. A change in one of the regulatory modules can alter one part of the expression pattern without affecting the rest, and without requiring changes in regulatory proteins that would have repercussions for the expression of other genes in the genome. As described in [Chapter 7](#), it is such regulatory DNA that contains the key to the complex organization of multicellular plants and animals, and its properties make possible the independent adaptability of each part of an organism's body structure in the course of evolution.

Most of the segmentation genes also have important functions at other times and places in the development of *Drosophila*. The *eve* gene, for example, is expressed in subsets of neurons, in muscle precursor cells, and in various other sites, under the control of additional enhancers (see [Figure 21-38](#)). By addition of new modules to its regulatory DNA, any gene can be coopted during evolution for new purposes at new sites in the body, without detriment to its other functions. [↑ TOP](#)

Egg-Polarity, Gap, and Pair-Rule Genes Create a Transient Pattern That Is Remembered by Other Genes

Within the first few hours after fertilization, the gap genes and the pair-rule genes are activated one after another. Their mRNA products appear first in patterns that only approximate the final picture; then, within a short time—through a series of interactive adjustments—the fuzzy initial distribution of gene products resolves itself into a regular, crisply defined system of stripes ([Figure 21-39](#)). But this system itself is unstable and transient. As the embryo proceeds through gastrulation and beyond, the regular segmental pattern of gap and pair-rule gene products disintegrates. Their actions, however, have stamped a permanent set of labels—positional values—on the cells of the blastoderm. These positional labels are recorded in the persistent activation of certain of the segment-polarity genes and of the homeotic selector genes, which serve to maintain the segmental organization of the larva and adult. The segment-polarity gene *engrailed* provides a good example. Its RNA transcripts are seen in the cellular blastoderm in a series of 14 bands, each approximately one cell wide, corresponding to the anteriormost portions of the future parasegments ([Figure 21-40](#)).

The segment-polarity genes are expressed in patterns that repeat from one parasegment to the next, and their bands of expression appear in a fixed relationship to the bands of expression of the pair-rule genes that help to induce them. However, the production of this pattern within each parasegment depends on interactions among the segment-polarity genes themselves. These interactions occur at stages when the blastoderm has already become fully partitioned into separate cells, so that cell-cell signaling of the usual sort has to come into play. A large subset of the segment-polarity genes code for components of two signal transduction pathways, the Wnt pathway and the Hedgehog pathway, including the secreted signal proteins Wingless (a Wnt family member) and Hedgehog. These are expressed in different bands of cells that serve as signaling centers within each parasegment, and they act to maintain and refine the expression of other segment-polarity genes. Moreover, although their initial expression is determined by the pair-rule genes, the two signaling proteins regulate one another's expression in a mutually supportive way, and they proceed to help trigger expression of genes such as *engrailed* in precisely the correct sites.

The *engrailed* expression pattern will persist throughout life, long after the signals that organized its production have disappeared (see [Figure 21-40](#)). This example illustrates not only the progressive subdivision of the embryo by means of more and more narrowly localized signals, but also the transition between the transient signaling events of early development and the later stable maintenance of developmental information.

Besides regulating the segment-polarity genes, the products of pair-rule genes collaborate with the products of gap genes to cause the precisely localized activation of a further set of spatial labels—the homeotic selector genes. It is the homeotic selector genes that permanently distinguish one parasegment from another. In the next section we examine these selector genes in detail and consider their role in cell memory. [↑ TOP](#)

Summary

The fly *Drosophila* has been the foremost model organism for study of the genetics of animal development. Like other insects, it begins its development with a series of nuclear divisions generating a syncytium, and a large amount of early patterning occurs in this single giant multinucleate cell. The pattern originates with asymmetry in the egg, organized both by localized deposits of mRNA inside the egg and by signals from the follicle cells around it. Positional information in the multinucleate embryo is supplied by four intracellular gradients that are set up by the products of four groups of maternal-effect genes called egg-polarity genes. These control four distinctions fundamental to the body plan of animals: dorsal versus ventral, endoderm versus mesoderm and ectoderm, germ cells versus somatic cells, and head versus rear.

The egg-polarity genes operate by setting up graded distributions of gene

regulatory proteins in the egg and early embryo. The gradients along the anteroposterior axis initiate the orderly expression of gap genes, pair-rule genes, segment-polarity genes, and homeotic selector genes. These, through a hierarchy of interactions, become expressed in some regions of the embryo and not others, progressively subdividing the blastoderm into a regular series of repeating modular units called segments. The complex patterns of gene expression reflect the modular organization of the regulatory *DNA*, with separate enhancers of an individual gene responsible for separate parts of its expression pattern.

The segment-polarity genes come into play toward the end of the segmentation process, soon after the syncytium has become partitioned into separate cells, and they control the internal patterning of each segment through cell-cell signaling via the Wnt (Wingless) and Hedgehog pathways. This leads to persistent localized activation of genes such as engrailed, giving cells a remembered record of their anteroposterior address within the segment. Meanwhile, a new cell-cell signaling gradient is also set up along the dorsoventral axis, with the TGF β family member Decapentaplegic (Dpp) and its antagonist, Short gastrulation, acting as the morphogens. This gradient helps to refine the assignment of different characters to cells at different dorsoventral levels. Homologous proteins are also known to control the patterning of the ventrodorsal axis in vertebrates. [↑ TOP](#)

Figure 21-25. The origins of the *Drosophila* body segments during embryonic development. The embryos are seen in side view in drawings (A-C) and corresponding scanning electron micrographs (D-F). (A and D) At 2 hours the embryo is at the *syncytial blastoderm* stage (see [Figure 21-51](#)) and no segmentation is visible, although a fate map can be drawn showing the future segmented regions (*color* in A). (B and E) At 5–8 hours the embryo is at the *extended germ band* stage: gastrulation has occurred, segmentation has begun to be visible, and the segmented axis of the body has lengthened, curving back on itself at the tail end so as to fit into the egg shell. (C and F) At 10 hours the body axis has contracted and become straight again, and all the segments are clearly defined. The head structures, visible externally at this stage, will subsequently become tucked into the interior of the larva, to emerge again only when the larva goes through pupation to become an adult. (D and E, courtesy of F.R. Turner and A.P. Mahowald, *Dev. Biol.* 50:95–108, 1976. © Academic Press; F, from J.P. Petschek, N. Perrimon, and A.P. Mahowald, *Dev. Biol.* 119:175–189, 1987. © Academic Press.)

Figure 21-26. The segments of the *Drosophila* larva and their correspondence with regions of the blastoderm. The parts of the embryo that become organized into segments are shown in color. The two ends of the embryo, shaded *gray*, are not segmented and become tucked into the interior of the body to form the internal structures of the head and gut. (The future external, segmental structures of the adult head are also transiently tucked into the interior in the larva.) Segmentation in *Drosophila* can be described in terms of either segments or parasegments: the relationship is shown in the middle part of the figure. Parasegments often correspond more simply to patterns of gene expression. The exact number of abdominal segments is debatable: eight are clearly defined, and a ninth is present vestigially in the larva, but absent in the adult.

Figure 21-29. The domains of the anterior, posterior, and terminal systems of egg-polarity genes. The *upper* diagrams show the fates of the different regions of the egg/early embryo and indicate (in *white*) the parts that fail to develop if the anterior, posterior, or terminal system is defective. The *middle* row shows schematically the appearance of a normal larva and of mutant larvae that are defective in a gene of the anterior system (for example, *bicoid*), of the posterior system (for example, *nanos*), or of the terminal system (for example, *torso*). The *bottom* row of drawings shows the appearances of larvae in which none or only one of the three gene systems is functional. The lettering beneath each larva specifies which systems are intact (A P T for a normal larva, -P T for a larva where the anterior system is defective but the posterior and terminal systems are intact, and so on). Inactivation of a particular gene system causes loss of the corresponding set of body structures; the body parts that form correspond to the gene systems that remain functional. Note that larvae with a defect in the anterior system can still form terminal structures at their anterior end, but these are of the type normally found at the rear end of the body rather than the front of the head. (Slightly modified from D. St. Johnston and C. Nüsslein-Volhard, *Cell* 68:201–219, 1992.)

Figure 21-30. A *Drosophila* oocyte in its follicle. The oocyte is derived from a germ cell that divides four times to give a family of 16 cells that remain in communication with one another via cytoplasmic bridges (*gray*). One member of the family group becomes the oocyte, while the others become nurse cells, which make many of the components required by the oocyte and pass them into it via the cytoplasmic bridges. The follicle cells that partially surround the oocyte have a separate ancestry. As indicated, they are the sources of terminal and ventral egg-polarizing signals.

Figure 21-35. The vertebrate body plan as a dorsoventral inversion of the insect body plan. The mechanism of dorsoventral patterning in a vertebrate embryo is discussed in more detail later in this chapter. Note the correspondence with regard to the circulatory system as well as the gut and nervous system. In insects, the circulatory system is represented by a tubular heart and a main dorsal blood vessel, which pumps blood out into the tissue spaces through one set of apertures and receives blood back from the tissues through another set. In contrast with vertebrates, there is no system of capillary vessels to contain the blood as it percolates through the tissues. Nevertheless, heart development depends on homologous genes in vertebrates and insects, reinforcing the relationship between the two body plans. (After E.L. Ferguson, *Curr. Opin. Genet. Dev.* 6:424–431, 1996.)

Figure 21-36. Examples of the phenotypes of mutations affecting the three types of segmentation genes. In each case the areas shaded in *green* on the normal larva (*left*) are deleted in the mutant or are replaced by mirror-image duplicates of the unaffected regions. By convention, dominant mutations are written with an initial capital letter and recessive mutations are written with a lower-case letter. Several of the patterning mutations of *Drosophila* are classed as dominant because they have a perceptible effect on the phenotype of the heterozygote, even though the characteristic major, lethal effects are recessive—that is, visible only in the homozygote. (Modified from C. Nüsslein-Volhard and E. Wieschaus, *Nature* 287:795–801, 1980.)

Figure 21-38. Modular organization of the regulatory DNA of the *eve* gene. In the experiment shown, cloned fragments of the regulatory DNA were linked to a *LacZ* reporter (a bacterial gene). Transgenic embryos containing these constructs were then stained by *in situ* hybridization to reveal the pattern of expression of *LacZ* (blue/black), and counterstained with an anti-Eve antibody (orange) to show the positions of the normal *eve* expression stripes. Different segments of the *eve* regulatory DNA (*ochre*) are thus found to drive gene expression in regions corresponding to different parts of the normal *eve* expression pattern. Two segments in tandem drive expression in a pattern that is the sum of the patterns generated by each of them individually. Separate regulatory modules are responsible for different times of gene expression, as well as different locations: the leftmost panel shows the action of a module that comes into play later than the others illustrated and drives expression in a subset of neurons. Development of Multicellular Organisms

Homeotic Selector Genes and the Patterning of the Anteroposterior Axis

As development proceeds, the body becomes more and more complex. In all this growing complexity there is, however, a simplifying feature that puts an understanding of the whole developmental process within our grasp. Again and again, in every species and at every level of organization, we find that complex structures are made by repeating a few basic themes with variations. Thus a limited number of basic differentiated cell types, such as muscle cells or fibroblasts, recur with subtle individual variations in different sites. These cell types are organized into a limited variety of tissue types, such as muscle or tendon, which again are repeated with subtle variations in different regions of the body. From the various tissues, organs such as teeth or digits are built—molars and incisors, fingers and thumbs and toes—a few basic kinds of structure, repeated with variations.

Wherever we find this phenomenon of *modulated repetition*, we can break down the developmental biologist's problem into two kinds of question: what is the basic construction mechanism common to all the objects of the given class, and how is this mechanism modified to give the observed variations? The embryo uses a combinatorial strategy to generate its complexity, and we can use a combinatorial strategy to understand it.

The segments of the insect body provide a very clear example. We have already sketched the way in which the rudiment of a single typical segment is constructed. We must now consider how one segment is caused to be different from another.

The HOX Code Specifies Anterior-Posterior Differences

The first glimpse of a genetic answer to the question of how each segment acquires its individual identity came over 80 years ago, with the discovery of the first of a set of mutations in *Drosophila* that cause bizarre disturbances of the organization of the adult fly. In the *Antennapedia* mutant, for example, legs sprout from the head in place of antennae ([Figure 21-41](#)), while in the *bithorax* mutant, portions of an extra pair of wings appear where normally there should

[Figure 21-41. A homeotic mutation.](#)

[Figure 21-46. Expression domains of Hox genes...](#)

[Figure 21-47. Segmentation and Hox gene expression...](#)

be the much smaller appendages called halteres. These mutations transform parts of the body into structures appropriate to other positions and are called *homeotic*. A whole set of **homeotic selector genes** determines the anteroposterior character of the segments of the fly.

The genes of this set—eight of them in the fly—are all related to one another as members of a multigene family, and they all lie in one or the other of two tight gene clusters known as the **bithorax complex** and the **Antennapedia complex**. The genes in the bithorax complex control the differences among the abdominal and thoracic segments of the body, while those in the Antennapedia complex control the differences among thoracic and head segments. Comparisons with other species show that the same genes are present in essentially all animals, including humans. These comparisons also reveal that the Antennapedia and bithorax complexes are the two halves of a single entity, called the Hox complex, that has become split in the course of the fly's evolution, and whose members operate in a coordinated way to exert their control over the head-to-tail pattern of the body. [↑ TOP](#)

Homeotic Selector Genes Code for DNA-Binding Proteins That Interact with Other Gene Regulatory Proteins

To a first approximation each homeotic selector gene is normally expressed in just those regions that develop abnormally when the gene is mutated or absent. The products of these genes can thus be viewed as molecular address labels possessed by the cells of each parasegment: they are the physical embodiment of the cells' positional value. If the address labels are changed, the parasegment behaves as though it were located somewhere else, and deletion of the entire complex results in a larva whose body segments are all alike ([Figure 21-42](#)).

A first problem, therefore, is to understand how the homeotic selector gene products act on the basic segment-patterning machinery to give each parasegment its individuality. The products of the homeotic selector genes are gene regulatory proteins, all related to one another by the possession of a highly conserved DNA-binding *homeodomain* (60 amino acids long), discussed in [Chapter 7](#). The corresponding segment in the DNA sequence is called a *homeobox* from which, by abbreviation, the Hox complex takes its name.

If the products of the homeotic selector genes are similar in their DNA-binding regions, how do they exert different effects so as to make one parasegment different from the next? The answer seems to lie largely in the parts of the proteins that do not bind directly to DNA but interact with other proteins in DNA-bound complexes. The different partners in these complexes act together with the homeotic selector proteins to dictate which DNA-binding sites will be recognized and whether the effect on transcription at those sites will be activation or repression. In this way, the products of the homeotic selector genes combine with other gene regulatory proteins and modulate their actions

Search

so as to give each parasegment its characteristic features. [↑ TOP](#)

The Homeotic Selector Genes Are Expressed Sequentially According to Their Order in the Hox Complex

To understand how the Hox complex provides cells with positional values, we also need to consider how the expression of the Hox genes themselves is regulated. The coding sequences of the eight homeotic selector genes in the Antennapedia and bithorax complexes are interspersed amid a much larger quantity—a total of about 650,000 nucleotide pairs—of regulatory DNA. This DNA includes binding sites for the products of egg-polarity and segmentation genes. The regulatory DNA in the Hox complex acts as an interpreter of the multiple items of positional information supplied to it by all these gene regulatory proteins. In response, a particular set of homeotic selector genes is transcribed, appropriate to the location.

In the pattern of control there is a remarkable regularity. The sequence in which the genes are ordered along the chromosome, in both the Antennapedia and the bithorax complexes, corresponds almost exactly to the order in which they are expressed along the axis of the body ([Figure 21-43](#)). This suggests that the genes are activated serially by some process that is graded—in duration or intensity—along the axis of the body, and whose action spreads gradually along the chromosome. The most "posterior" of the genes expressed in a cell generally dominates, driving down expression of the previously activated "anterior" genes and dictating the character of the segment. The gene regulatory mechanisms underlying these phenomena are still not well understood, but their consequences are profound. We shall see that the serial organization of gene expression in the Hox complex is a fundamental feature that has been highly conserved in the course of evolution.

There are hundreds of other homeobox-containing genes in the genome of the fly—and of other animal species—but most of them are scattered and not clustered in complexes such as the Hox complex. They have many different gene regulatory functions, but a substantial proportion of them have roles akin to that of the Hox genes: they control the variations on a basic developmental theme. Different classes of neurons, for example, are often distinguished from one another by expression of specific genes of this large superfamily. [↑ TOP](#)

The Hox Complex Carries a Permanent Record of Positional Information

The spatial pattern of expression of the genes in the Hox complex is set up by signals acting early in development, but the consequences are long-lasting. Although the pattern of expression undergoes complex adjustments as development proceeds, the Hox complex behaves in each cell as though stamped with a permanent record of the anteroposterior position that the cell

occupied in the early embryo. In this way, the cells of each segment are equipped with a long-term memory of their location along the anteroposterior axis of the body—in other words, with an anteroposterior positional value. As we shall see in the next section, the memory trace imprinted on the Hox complex governs the segment-specific identity not only of the larval segments, but also of the structures of the adult fly, which are generated at a much later stage from the larval imaginal discs and other nests of imaginal precursor cells in the larva.

The molecular mechanism of the cell memory for this positional information relies on two types of regulatory inputs. One is from the homeotic selector genes themselves: many of the Hox proteins autoactivate the transcription of their own genes. Another crucial input is from two large complementary sets of transcriptional regulators called the *Polycomb group* and the *Trithorax group*. If these regulators are defective, the pattern of expression of the homeotic selector genes is set up correctly at first but is not correctly maintained as the embryo grows older.

The two sets of regulators act in opposite ways. Trithorax group proteins are needed to maintain the transcription of Hox genes in cells where transcription has already been switched on. In contrast, Polycomb group proteins form stable complexes that bind to the chromatin of the Hox complex and maintain the repressed state in cells where Hox genes have not been activated at the critical time ([Figure 21-44](#)). The developmental memory involves acetylation of histone H4 at specific regulatory sites in the chromatin adjacent to the Hox genes; the proteins of the Trithorax and Polycomb groups act somehow to perpetuate the H4 state—hyperacetylated if the target Hox gene has been transiently exposed at embryonic stages to an activator of gene transcription, not acetylated in this way otherwise (see [Figure 4-48](#)). [↑ TOP](#)

The Anteroposterior Axis Is Controlled by Hox Selector Genes in Vertebrates Also

Homologs of the *Drosophila* homeotic selector genes have been found in almost every animal species studied, from cnidarians (hydroids) and nematodes to molluscs and mammals. Remarkably, these genes are often grouped in complexes similar to the insect Hox complex. In the mouse there are four such complexes—called the HoxA, HoxB, HoxC, and HoxD complexes—each on a different chromosome. Individual genes in each complex can be recognized by their sequences as counterparts of specific members of the *Drosophila* set. Indeed, mammalian Hox genes can function in *Drosophila* as partial replacements for the corresponding *Drosophila* Hox genes. It appears that each of the four mammalian Hox complexes is, roughly speaking, the equivalent of a complete insect complex (that is, an Antennapedia complex plus a bithorax complex) ([Figure 21-45](#)).

The ordering of the genes within each vertebrate Hox complex is essentially

the same as in the insect Hox complex, suggesting that all four vertebrate complexes originated by duplications of a single primordial complex and have preserved its basic organization. Most tellingly, when the expression patterns of the Hox genes are examined in the vertebrate embryo by *in situ* hybridization, it turns out that the members of each complex are expressed in a head-to-tail series along the axis of the body, just as they are in *Drosophila* (Figure 21-46). The pattern is most clearly seen in the neural tube, but is also visible in other tissues, especially the mesoderm. With minor exceptions this anatomical ordering matches the chromosomal ordering of the genes in each complex, and corresponding genes in the four different Hox complexes have almost identical anteroposterior domains of expression.

The gene expression domains define a detailed system of correspondences between insect body regions and vertebrate body regions (see Figure 21-45). The parasegments of the fly correspond to a similarly labeled series of segments in the anterior part of the vertebrate embryo. As shown in Figure 21-47, these are most clearly demarcated in the hindbrain, where they are called *rhombomeres*. In the tissues lateral to the hindbrain the segmentation is seen in the series of *branchial arches*, prominent in all vertebrate embryos—the precursors of the system of gills in fish and of the jaws and structures of the neck in mammals; each pair of rhombomeres in the hindbrain corresponds to one branchial arch (Figure 21-47). In the hindbrain, as in *Drosophila*, the boundaries of the expression domains of many of the Hox genes are aligned with the boundaries of the anatomical segments.

The products of the mammalian Hox genes appear to specify positional values that control the anteroposterior pattern of parts in the hindbrain, neck, and trunk. Eliminating the function of a Hox gene in the mouse leads to a defect in a body region that corresponds to the domain of expression of that gene. Sometimes the affected body region is transformed into a more anterior body region, as in *Drosophila* homeotic mutants; sometimes the affected body region dies or fails to grow. The transformations observed in mouse Hox mutants are often incomplete, perhaps because of a redundancy between genes in the four Hox gene clusters. But it seems clear that the fly and the mouse use essentially the same molecular machinery to give individual characters to successive regions along at least a part of their anteroposterior axis. [↑ TOP](#)

Summary

The complexity of the adult body of an animal is built up by modulated repetition of a few basic types of structure. Thus, superimposed on the pattern of gene expression that repeats itself in every segment, there is a serial pattern of expression of homeotic selector genes that confer on each segment a different identity. The homeotic selector genes code for DNA-binding proteins of the homeodomain family. They are grouped in the *Drosophila* genome in two clusters, called the Antennapedia and bithorax complexes, believed to be the two parts of a single primordial Hox complex that became split during

evolution of the fly. In each complex, the genes are arranged in a sequence that matches their sequence of expression along the axis of the body. Hox gene expression is initiated in the embryo. It is maintained subsequently by the action of DNA-binding proteins of the Polycomb and Trithorax group, which stamp the chromatin of the Hox complex with a heritable record of its embryonic state of activation. Hox complexes homologous to that of *Drosophila* are found in virtually every type of animal that has been examined, from cnidarians to humans, and they appear to have an evolutionarily conserved role in patterning the anteroposterior axis of the body. Mammals have four Hox complexes, each showing a similar relationship between a serial arrangement of the genes in the chromosome and their serial pattern of expression along the body axis. the genes of the Hox complex. The sequence of genes in each of the two subdivisions of the chromosomal complex corresponds to the spatial sequence in which the genes are expressed. Note that most of the genes are expressed at a high level throughout one parasegment (*dark color*) and at a lower level in some adjacent parasegments (*medium color* where the presence of the transcripts is necessary for a normal phenotype, *light color* where it is not). In regions where the expression domains overlap, it is usually the most "posterior" of the locally active genes that determines the local phenotype. The drawings in the lower part of the figure represent the gene expression patterns in embryos at the extended germ band stage, about 5 hours after fertilization.

Figure 21-45. The Hox complex of an insect and the Hox complexes of a mammal compared and related to body regions. The genes of the Antennapedia and bithorax complexes of *Drosophila* are shown in their chromosomal order in the *top line*; the corresponding genes of the four mammalian Hox complexes are shown *below*, also in chromosomal order. The gene expression domains in fly and mammal are indicated in a simplified form by color in the cartoons of animals *above* and *below*. However, the details of the patterns depend on developmental stage and vary somewhat from one mammalian Hox complex to another. Also, in many cases, genes shown here as expressed in an anterior domain are also expressed more posteriorly, overlapping the domains of more posterior Hox genes (see, for example, [Figure 21-46](#)). The complexes are thought to have evolved as follows: first, in some common ancestor of worms, flies, and vertebrates, a single primordial homeotic selector gene underwent repeated duplication to form a series of such genes in tandem—the ancestral Hox complex. In the *Drosophila* sublineage this single complex became split into separate Antennapedia and bithorax complexes. Meanwhile, in the lineage leading to the mammals the whole complex was repeatedly duplicated to give four Hox complexes. The parallelism is not perfect because apparently some individual genes have been duplicated, others lost, and still others coopted for different purposes (genes in parentheses in the *top line*) since the complexes diverged. (Based on a diagram kindly supplied by William McGinnis.)

Figure 21-46. Expression domains of Hox genes in a mouse. The photographs show whole embryos displaying the expression domains of two genes of the HoxB complex (*blue* stain). These domains can be revealed by *in situ* hybridization or, as in these examples, by constructing transgenic mice containing the control sequence of a Hox gene coupled to a *LacZ* reporter gene, whose product is detected histochemically. Each gene is expressed in a long expanse of tissue with a sharply defined anterior limit. The earlier the position of the gene in its chromosomal complex, the more anterior the anatomical limit of its expression. Thus, with minor exceptions, the anatomical domains of the successive genes form a nested set, ordered according to the ordering of the genes in the chromosomal complex. (Courtesy of Robb Krumlauf.)

Development of Multicellular Organisms → Homeotic Selector Genes and the Patterning of the Anteroposterior Axis

Figure 21-47. Segmentation and Hox gene expression in the hindbrain, as seen in a chick embryo. The pattern of HoxB gene expression is indicated by coloring as in [Figure 21-45](#). For simplicity, the expression in tissues other than the central nervous system is not shown. In regions where the expression domains of two or more Hox genes overlap, the coloring corresponds to the most "posterior" of the genes expressed. Just as the expression domains in the fly are related to parasegments, so the expression domains in the vertebrate are related to the rhombomeres (segments in the hindbrain). Each pair of rhombomeres is associated with a branchial arch (a modified gill rudiment), to which it sends innervation. The pattern of Hox gene expression in the branchial arches (not shown) matches that in the associated rhombomeres. In the spinal cord, there are no rhombomere boundaries, and the expression domains of the different posterior Hox genes overlap.

Development of Multicellular Organisms

Organogenesis and the Patterning of Appendages

We have seen that the segments of the insect larva are all variations on the same basic theme, with segmentation genes defining the basic repetitive module and homeotic selector genes giving each segment its individual character. The same applies to the major appendages of the adult insect body—legs, wings, antennae, mouthparts and external genitalia: they too are variations on a common basic theme. At a finer level of detail, we encounter the same wonderful simplification: the appendages—and many other parts of the body—consist of substructures that are themselves variations on a small number of basic evolutionarily conserved themes.

In this section we follow the course of development in *Drosophila* through to its end, narrowing our focus at each step to examine one example of the many related structures that are developing in parallel. As we go along, we shall point out parallels with vertebrate structures that develop similarly, using not only the same general strategies, but many of the same specific molecular mechanisms. But to avoid interrupting the narrative later, we must first briefly explain some key experimental methods, required to cope with a special problem that arises when we try to discover how genes control the later stages of development.

Conditional and Induced Somatic Mutations Make it Possible to Analyze Gene Functions Late in Development

As emphasized earlier, the same gene may be used repeatedly in many different situations—in different regions of the body, and at different times. Often, loss-of-function mutations disrupt early development so severely that the embryo or larva dies, depriving us of the opportunity to see how the mutation would affect later processes.

One way around this problem is to study conditional mutations. If we have, for example, a temperature-sensitive mutation in the gene of interest, we can maintain the animal during early development at a low temperature, where the gene product functions normally, and then disable the gene product whenever we please by raising the temperature to discover the late functions.

Other methods involve actually modifying the DNA in subsets of cells at late stages of development—a sort of genetic surgery on individual cells that allows mutant groups of cells of a specified genotype to be generated at a chosen time in development. This remarkable feat can be achieved by *induced somatic recombination*. A current version of this technique uses transgenic flies that have been bred to contain two types of yeast-derived genetic elements: the FLP site-specific recombinase gene, and the FLP Recombinase Target (FRT) sequence. Typically, the animal is homozygous for an insertion of the FRT sequence close to the centromere on a chosen chromosome arm, while a construct consisting of the FLP gene under a heat-shock promoter is inserted elsewhere in the genome. If such a transgenic embryo or larva is given a heat shock (that is, exposed to a high temperature for a few minutes), expression of FLP is induced, and this enzyme catalyzes crossing-over and recombination between the maternal and paternal chromosomes at the FRT site. If the heat shock is adjusted to be sufficiently mild, this event will occur in only one or a few cells, scattered at random. As explained in [Figure 21-48](#), if the animal is also heterozygous for a gene of interest in the crossed-over chromosomal region, the process can result in a pair of daughter cells that are homozygous, the one receiving two copies of the maternal allele of the gene, the other receiving two copies of the paternal allele. Each of these daughter cells will normally grow and divide to give clonal patches of homozygous progeny.

The occurrence of the cross-over can be detected if the animal is chosen to be also heterozygous for a mutation in a marker gene—a pigmentation gene, for example—that lies on the same chromosome arm as the gene of interest and so undergoes crossing over in company with it. In this way clearly marked homozygous mutant clones of cells can be created to order. Either FLP and FRT, or the analogous Cre and Lox pair of recombination elements, can also be used in other configurations to switch expression of a gene on or off (see [Figure 5-82](#)). With these techniques, one can discover what happens, for example, when cells are caused to produce a particular signaling molecule at an abnormal site, or are deprived of a particular receptor.

Instead of using a heat-shock promoter to drive expression of the FLP recombinase, one can use a copy of the regulatory sequence of a gene in the fly's normal genome that is expressed at some interesting time and place. The recombination event will then be triggered, and mutant cells created, at just the sites where that gene is normally expressed. A variant of this technique uses transcriptional regulation machinery borrowed from yeast, rather than genetic recombination machinery, to switch expression of a chosen fly gene reversibly on or off according to the normal pattern of expression of some other chosen fly gene ([Figure 21-49](#)).

By switching gene functions off or on at specific times and places in these ways, developmental biologists can set about deciphering the system of genetically specified signals and responses that control the patterning of any

organ of the body. [↑ TOP](#)

Body Parts of the Adult Fly Develop From Imaginal Discs

The external structures of the adult fly are formed largely from rudiments called imaginal discs—groups of cells that are set aside, apparently undifferentiated, in each segment of the larva. The discs are pouches of epithelium, shaped like crumpled and flattened balloons, and continuous with the epidermis (the surface layer) of the larva. There are 19 of them, arranged as 9 pairs on either side of the larva plus 1 disc in the midline (Figure 21-50).

They grow and develop their internal pattern as the larva grows, until finally, at metamorphosis, they evert (turn inside out), extend, and differentiate overtly to form the epidermal layer of the adult. The eyes and antennae develop from one pair of discs, the wings and part of the thorax from another, the first pair of legs from another, and so on. [↑ TOP](#)

Homeotic Selector Genes Are Essential for the Memory of Positional Information in Imaginal Disc Cells

The cells of one imaginal disc look like those of another, but grafting experiments show that they are in fact already regionally determined and nonequivalent. If one imaginal disc is transplanted into the position of another in the larva and the larva is then left to go through metamorphosis, the grafted disc is found to differentiate autonomously into the structure appropriate to its origin: a wing disc will give wing structures, a haltere disc, haltere structures, regardless of its new site. This shows that the imaginal disc cells are governed by a memory of their original position. By a more complex serial grafting procedure that lets the imaginal disc cells proliferate for an extended period before differentiating, it can be shown that this cell memory is stably heritable (with rare lapses) through an indefinitely large number of cell generations.

The homeotic selector genes are essential components of the memory mechanism. If, at any stage in the long period leading up to differentiation at metamorphosis, both copies of a homeotic selector gene are eliminated by induced somatic recombination from a clone of imaginal disc cells that would normally express that gene, those cells will differentiate into incorrect structures, as though they belonged to a different segment of the body. These and other observations indicate that each cell's memory of positional information depends on the continued activity of the homeotic selector genes. This memory, furthermore, is expressed in a cell-autonomous fashion—each cell appears to maintain its state individually, depending on its own history and genome. [↑ TOP](#)

Specific Regulatory Genes Define the Cells That Will Form an Appendage

Search

PubMed

We must now examine how an appendage develops its internal pattern. We shall take the insect wing as our example.

The process begins with the early patterning mechanisms we have already discussed. The anteroposterior and dorsoventral systems of signals in the early embryo in effect mark out an orthogonal grid in the blastoderm, in the form of dorsoventral, anteroposterior, and periodically spaced segmental gene expression boundaries. At certain points of intersection of these boundaries, the combination of genes expressed is such as to switch a cluster of cells into the imaginal disc pathway.

In molecular terms this corresponds to switching on expression of imaginal-disc-defining regulatory genes. In most of the discs, the gene *Distal-less* is switched on. This codes for a gene regulatory protein that is essential for the sustained growth required to create an elongated appendage such as a leg or an antenna with a proximodistal axis. In its absence, such appendages fail to form, and when it is artificially expressed at abnormal sites, misplaced appendages can be produced. *Distal-less* is expressed in a similar fashion in the developing limbs and other appendages of most species of invertebrates and vertebrates that have been examined (Figure 21-51). For the eye disc, another gene, *eyeless* (together with two closely related genes), performs the corresponding role; it too has homologues with homologous functions—the *Pax-6* genes that drive eye development in other species, as discussed in [Chapter 7](#). [↑ TOP](#)

The Insect Wing Disc Is Divided into Compartments

From the outset, the cluster of cells forming the imaginal disc has the rudiments of an internal pattern, inherited from the earlier patterning process. For example, the cells in the posterior half of the wing-disc rudiment (and of most of the other imaginal-disc rudiments) express the segment-polarity gene *engrailed*, while those in the anterior half do not. The initial asymmetries lay the foundations for a subsequent more detailed patterning, just as in the egg and early embryo.

The sectors of the wing disc defined by these early differences of gene expression correspond to specific parts of the future wing. The posterior, *engrailed*-expressing region will form the posterior half of the wing, while the region that does not express *engrailed* will form the anterior half. Meanwhile, the dorsal part of the wing disc expresses a gene called *apterous*, while the ventral half does not. At metamorphosis, the disc folds along the line separating these domains to give a wing whose dorsal sheet of cells is derived from the *apterous*-expressing region and whose ventral sheet is derived from the region that does not express *apterous*. The wing margin, where these two epithelial sheets are joined, corresponds to the boundary of the *apterous* expression domain in the disc (Figure 21-52).

The cells of the disc, having switched on expression of the genes that mark

them as anterior or posterior, dorsal or ventral, retain this specification as the disc grows and develops. Because the cells are sensitive to these differences and selective in their choice of neighbors, sharply defined boundaries are formed between the four resultant sets of cells, with no mixing at the interfaces. The four corresponding quadrants of the disc are called compartments, because there is no exchange of cells between them ([Figure 21-53](#)). [↑ TOP](#)

Four Familiar Signaling Pathways Combine to Pattern the Wing Disc: Wingless, Hedgehog, Dpp, and Notch

Along each of the compartment boundaries—the anteroposterior boundary defined by *engrailed* and the dorsoventral boundary defined by *apterous*—cells in different states confront one another and interact to create narrow bands of specialized cells. These boundary cells produce new signals to organize the subsequent growth and more detailed patterning of the appendage.

Cells in the posterior wing compartment express the Hedgehog signaling protein, but cannot respond to it. Cells in the anterior compartment can respond to Hedgehog. Because Hedgehog acts only over a short distance, the signal reception pathway is activated only in the narrow band of cells just anterior to the compartment boundary, where anterior and posterior cells are juxtaposed. These boundary cells respond by switching on expression of another signaling molecule, Dpp—the same protein that we encountered previously, in the dorsoventral patterning of the early embryo ([Figure 21-54](#)). Dpp acts in its new context in much the same way as before: it is thought to diffuse (or somehow spread its effects) outward from the boundary cells, setting up a morphogen gradient to control the subsequent detailed pattern of growth and gene expression.

Analogous events occur at the dorsoventral compartment boundary (see [Figure 21-54](#)). Here, at the future wing margin, short-range communication mediated by the Notch pathway creates a band of boundary cells that produce another morphogen, the Wingless protein—the same signaling factor, belonging to the Wnt family, that acted earlier in the anteroposterior patterning of each embryonic segment. The Dpp and Wingless gradients, together with the other signals and asymmetries of gene expression that we have discussed, combine to drive expression of other genes at precisely defined locations within each compartment. [↑ TOP](#)

The Size of Each Compartment Is Regulated by Interactions Among Its Cells

One of the most mysterious and ill-understood aspects of animal development is the control of growth: why does each part of the body grow to a precisely defined size? This problem is exemplified in remarkable way in the imaginal

discs of *Drosophila*. By induced somatic recombination, one can, for example, create a clonal patch of cells that proliferate more rapidly than the rest of the cells in the developing organ. The clone may grow to occupy almost the whole of the compartment in which it lies, and yet it does not overstep the boundary of the compartment. Astonishingly, its rapid growth has almost no effect on the compartment's final size, its shape, or even the details of its internal pattern (see [Figure 21-53](#)). Somehow, the cells within the compartment interact with one another to determine when their growth should stop, and each compartment behaves as a regulatory unit in this respect.

A first question is whether the size of the compartment is regulated so as to contain a set number of cells. Mutations in components of the cell-cycle control machinery can be used to speed up or slow down the rate of cell division without altering the rate of cell or tissue growth. This results in abnormally large numbers of abnormally small cells, or the converse, but the size—that is, the area—of the compartment is practically unchanged. Thus, the regulatory mechanism seems to depend on signals that indicate the physical distance between one part of the compartment and another, and on cellular responses that somehow read these signals so as to halt growth only when the tissue has attained the correct area.

One clue to how the system works comes from the observation that flies with genetic defects in the signaling pathway mediated by insulin and insulin-like factors are small, with cells that are both small and reduced in numbers, while overactivity of this pathway can produce giant flies, with more and bigger cells. Localized misexpression of the same genes in a single compartment has similar effects on just that compartment. Since insulin is widely used in animals as a regulator of responses to nutrition, the mechanisms controlling the sizes of compartments and organs may have evolved from mechanisms that control cell growth and proliferation according to nutritional conditions.

The deeper problem remains, however: what mechanism ensures that each little piece of the pattern within a compartment grows to its appropriate size, despite local disturbances in growth rate or starting conditions? The morphogen gradients (of Dpp and Wingless, for example) create a pattern by imposing different characters on cells in different positions. Could it be that the cells in each region can somehow sense how close the spacing of the pattern is—how steep the gradient of change in cell character—and continue their growth until the tissue is spread out to the right degree? A striking demonstration of the phenomenon that needs to be understood is seen in the intercalary regeneration that occurs when separate parts of a *Drosophila* imaginal disc or of a growing cockroach leg are surgically grafted together. After the graft, the cells in the neighbourhood of the junction proliferate and fill in the parts of the pattern that should normally lie between them, continuing their growth until the normal spacing between landmarks is restored ([Figure 21-55](#)). The mechanisms that bring this about are a mystery, but it seems likely that they are similar to the mechanisms that regulate growth during normal development. [↑ TOP](#)

Similar Mechanisms Pattern the Limbs of Vertebrates

The limbs of vertebrates seem very different from those of insects. The insect wing, for example, consists mainly of two elaborately patterned sheets of epithelium, with very little tissue in between. In contrast, a limb of a vertebrate consists of an elaborately patterned system of muscles, bones and other connective tissues inside a thin and much more simply structured covering of epidermis. Moreover, the evolutionary evidence suggests that the last common ancestor of insects and vertebrates may have had neither legs, nor arms, nor wings, nor fins and that we have evolved these various appendages independently. And yet, when we examine the molecular mechanisms that control vertebrate limb development, we find a surprising number of similarities with the limbs of insects. We have already mentioned some of these resemblances, but there are many others: almost all the molecules we have already mentioned in the fly wing have their counterparts in the vertebrate limb, although these are expressed in different spatial relationships.

The parallels have been most thoroughly studied in the chick embryo. As we saw earlier, each leg or wing of a chick originates from a tongue-shaped limb bud, consisting of a mass of embryonic connective tissue cells, called mesenchyme cells, encased in a jacket of epithelium. In this structure, one finds expression of homologs of almost all the genes that we have mentioned in our account of *Drosophila* wing patterning, including *Distal-less*, *wingless*, *Notch*, *engrailed*, *dpp*, and *hedgehog*, mostly performing functions that seem more or less similar to their functions in the *Drosophila* wing disc ([Figure 21-56](#)).

The Hox genes likewise make an appearance in the limbs of both insects and vertebrates. In the insect appendage, the anterior and posterior compartments are distinguished by expression of different genes of the Hox complex—a result of the serial expression pattern of these genes along the anteroposterior axis of the body as a whole. In the vertebrate limb, genes of two of the vertebrate Hox complexes (HoxA and HoxD) are expressed in a regular pattern, obedient to the usual rules of serial expression of genes in these complexes. They help, in conjunction with other factors such as the Tbx proteins mentioned earlier (see [Figure 21-9](#)), to regulate differences of cell behavior along the proximodistal limb axis.

According to one view, these molecular resemblances between developing limbs in different phyla reflect descent from a common ancestor that, while lacking limbs, had appendages of some sort built on similar principles—antennae, perhaps, or protruding mouthparts for snatching food. Modern limblike appendages, from the wings and legs of the fly to the arms and legs of a human, would then have evolved through activation of the genes for appendage formation at new sites in the body, as a result of changes in gene regulation. [↑ TOP](#)

Localized Expression of Specific Classes of Gene Regulatory Proteins Foreshadows Cell Differentiation

We now pick up again the thread of development in the *Drosophila* imaginal disc and follow it through to the final step at which cells become terminally differentiated. Narrowing our focus further, we take as our example the differentiation of just one type of small structure that arises in the imaginal disc epithelium: the **sensory bristle**.

The bristles that cover the body surface of an insect are miniature sense organs. Some respond to chemical stimuli, others to mechanical stimuli, but they are all constructed in a similar way. The structure is seen at its simplest in the mechanosensory bristles. Each of these consists of four cells: a shaft cell, a socket cell, a neural sheath cell, and a neuron ([Figure 21-57](#)). Movement of the shaft of the bristle excites the neuron, which sends a signal to the central nervous system.

The cells of the bristle of the adult fly derive from the imaginal disc epithelium, and all four of them are granddaughters or great-granddaughters (see [Figure 21-57](#)) of a single *sensory mother cell* that becomes distinct from the neighboring prospective epidermal cells during the last larval instar ([Figure 21-58](#)). (A fifth descendant migrates away from the rest to become a glial cell.) To account for the pattern of bristle differentiation, we have to explain first how the genesis of sensory mother cells is controlled and then how the five descendants of each such cell become different from one another.

Two genes, called *achaete* and *scute*, are crucial in initiating the formation of bristles in the imaginal disc epithelium. These genes have similar and overlapping functions and code for closely related gene regulatory proteins of the basic helix-loop-helix class (see [Chapter 7](#)). As a result of disc-patterning mechanisms of the type we have already discussed, *achaete* and *scute* are expressed in the imaginal disc in the regions within which bristles will form. Mutations that eliminate the expression of these genes at some of their usual sites block development of bristles at just those sites, and mutations that cause expression in additional, abnormal sites cause bristles to develop there. But expression of *achaete* and *scute* is transient, and only a minority of the cells initially expressing the genes go on to become sensory mother cells; the others become ordinary epidermis. The state that is specified by expression of *achaete* and *scute* is called *proneural*, and *achaete* and *scute* are called **proneural genes**. The proneural cells are primed to take the neurosensory pathway of differentiation, but, as we shall see, which of them will actually do so depends on competitive interactions among them. [↑ TOP](#)

Lateral Inhibition Singles Out Sensory Mother Cells Within Proneural Clusters

Cells expressing the proneural genes occur in groups in the imaginal disc epithelium—a small, isolated cluster of fewer than 30 cells for a big isolated bristle, a broad, continuous patch of hundreds or thousands of cells for a field of small bristles. In the former case just one member of the cluster becomes a sensory mother cell; in the latter case many cells scattered throughout the proneural region do so. In either case, each sensory mother cell becomes surrounded by cells that switch off expression of the proneural genes and become condemned to differentiate as epidermis instead. Experiments with genetic mosaics show that this is because a cell that becomes committed to the sensory-mother-cell pathway of differentiation sends a signal to its neighbors not to do the same thing: it exerts a *lateral inhibition*. If a cell that would normally become a sensory mother is genetically disabled from doing so, a neighboring proneural cell, freed from lateral inhibition, will become a sensory mother cell instead.

The lateral inhibition is mediated by the Notch signaling pathway. The cells in the cluster initially all express both the transmembrane receptor Notch and its transmembrane ligand Delta. Wherever Delta activates Notch, an inhibitory signal is sent into the Notch-expressing cell; consequently, all the cells in the cluster initially inhibit one another. However, receipt of the signal in a given cell is thought to diminish not only that cell's tendency to specialize as a sensory mother cell, but also its ability to fight back by delivering the inhibitory Delta signal in return. This creates a competitive situation, from which a single cell in each small region—the future sensory mother cell—emerges as winner, sending a strong inhibitory signal to its immediate neighbors but receiving no such signal in return ([Figure 21-59](#)). The consequences of a failure of this regulatory mechanism are shown in [Figure 21-60](#). [↑ TOP](#)

Lateral Inhibition Drives the Progeny of the Sensory Mother Cell Toward Different Final Fates

The same lateral inhibition mechanism dependent on Notch operates repeatedly in the formation of bristles—not only to force the neighbors of sensory mother cells to follow a different pathway and become epidermal, and but also later to make the daughters, the granddaughters, and finally the great-granddaughters of the sensory mother cell express different genes so as to form the different components of the bristle. At each stage, lateral inhibition mediates a competitive interaction that forces adjacent cells to behave in contrasting ways. Using a temperature-sensitive Notch mutation, it is possible to switch off Notch signaling after the sensory mother cell has been singled out, but before it has divided. The progeny then differentiate alike, giving a cluster of neurons in place of the four different cell types of a bristle.

Like many other competitions, those mediated by lateral inhibition are often rigged: one cell starts with an advantage that guarantees it will be the winner. In the development of the different cell types of the sensory bristle, a strong

initial bias is provided by an asymmetry in each of the cell divisions of the sensory mother cell and its progeny. A protein called Numb (together with certain other proteins) becomes localized at one end of the dividing cell, so that one daughter inherits the Numb protein and the other does not ([Figure 21-61](#)). Numb interacts with Notch, blocking its activity. Thus the Numb-containing cell is deaf to inhibitory signals from its neighbors while its sister remains sensitive. Since both cells initially express the Notch ligand Delta, the cell that has inherited Numb proceeds to become neural, while driving its sister toward a nonneural fate. [↑ TOP](#)

Planar Polarity of Asymmetric Divisions is Controlled by Signaling via the Receptor Frizzled

For the Numb mechanism to operate, there must be machinery in the dividing cell to segregate the determinant to one side of the cell before division. In addition, as the cell enters mitosis the mitotic spindle must be aligned with this asymmetry so that the determinant is allocated to just one daughter cell, and not shared out to both daughters at the time of cell division. In the above case, the sensory mother cell, at its first division, regularly divides to give an anterior cell that inherits Numb and a posterior cell that does not. This type of polarity in the plane of the epithelium is called *planar polarity* (in contradistinction to apico-basal polarity, where the cellular asymmetry is perpendicular to the plane of the epithelium). It is manifested in the uniformly backward-pointing orientation of the bristles, giving the fly its wind-swept appearance ([Figure 21-62](#)).

The planar polarity in the initial division of the sensory mother cell is controlled by a signaling pathway similar to the one that we encountered controlling asymmetric divisions in the nematode (see [Figure 21-20](#)), depending on the receptor Frizzled. Frizzled proteins have been discussed in [Chapter 15](#) as receptors for Wnt proteins, but in the control of planar polarity—in flies and probably in vertebrates too—this pathway functions in a special way: the intracellular relay mechanism exerts its main effects on the actin cytoskeleton, rather than on gene expression. The intracellular protein Dishevelled, downstream from Frizzled, is common to the gene-regulatory and the actin-regulatory branches of the signaling pathway. Separate domains of the Dishevelled molecule can be shown to be responsible for the two functions ([Figure 21-63](#)). Frizzled and Dishevelled both take their names from the unkempt look of flies where bristle polarity is disordered. [↑ TOP](#)

Lateral Inhibition and Asymmetric Division Combine to Regulate Genesis of Neurons Throughout the Body

The mechanisms we have described for controlling the genesis of neurons of sensory bristles operate also, with minor variations, in the genesis of virtually all other neurons—not only in insects, but also in other phyla. Thus in the

embryonic central nervous system, both in flies and in vertebrates, neurons are generated in regions of expression of proneural genes akin to *achaete* and *scute*. The nascent neurons or neuronal precursors express Delta and inhibit their immediate neighbors, which express Notch, from becoming committed to neural differentiation at the same time. When Notch signaling is blocked, inhibition fails, and in the proneural regions neurons are generated in huge excess at the expense of non-neuronal cells ([Figure 21-64](#)).

In many of these processes of neurogenesis, as in the development of the sensory bristle, asymmetric cell divisions play an important part, although the details, and the relationship to Notch signaling, are variable. Thus, in the embryonic central nervous system of *Drosophila*, the nerve-cell precursors, or *neuroblasts*, are singled out from the neurogenic ectoderm by a typical lateral-inhibition mechanism that depends on Notch, but then undergo asymmetric divisions in which the cells are polarized apico-basally. The localization of a set of neuronal cell-fate determinants at one end of the neuroblast is ultimately directed, in this case, by Bazooka, an apically localized protein that has a fundamental role in defining the apico-basal polarity of epithelia in general and is also involved in neurogenesis in the central nervous system of vertebrates. Bazooka is homologous to Par-3, one of the Par proteins that govern the asymmetric cell divisions in the early nematode embryo. [↑ TOP](#)

Notch Signaling Regulates the Fine-Grained Pattern of Differentiated Cell Types in Many Different Tissues

The process of lateral inhibition and cell diversification, initiated by expression of proneural genes and mediated by Notch, has turned out to be crucial for the fine-grained patterning of an enormous variety of different tissues. In the fly, it controls the production not only of neurons but also of many other differentiated cell types—for example, in muscle, in the lining of the gut, in the excretory system, in the tracheae, and in the eye and other sense organs. In vertebrates, homologs of the proneural genes and of Notch and its ligands are expressed in the corresponding tissues and have similar functions: mutations in the Notch pathway upset the balance not only of neurons and non-neuronal cells in the central nervous system, but also of the different specialized cell types in the lining of the gut, of endocrine and exocrine cells in the pancreas, and of sensory and supporting cells in sense organs such as the ear, to give only a few examples.

In all these tissues, a balanced mixture of different cell types is required. Notch signaling provides the means to generate the mixture, by enabling individual cells expressing one set of genes to direct their immediate neighbors to express another set. [↑ TOP](#)

Some Key Regulatory Genes Define a Cell Type; Others Can Activate the Program for Creation of an Entire Organ

The final choice of a particular mode of differentiation is marked by expression of specific cell-differentiation genes in the aftermath of the interactions mediated by Notch. Each cell type must express a whole collection of genes to perform its differentiated function, but the expression of these genes is coordinated by a much smaller set of high-level regulators. These regulators are sometimes called "master regulatory proteins" (though even they can exert their specific effect only in combination with the right partners, in a cell that is adequately primed). An example is the MyoD family of gene regulatory proteins (MyoD, myogenin, Myf5, MRF4 and their homologs in invertebrates). These proteins drive cells to differentiate as muscle, expressing muscle-specific actins and myosins and all the other cytoskeletal, metabolic and membrane proteins that a muscle cell needs (see [Figure 7-72](#)).

The gene regulatory proteins that define particular cell types often belong (as do MyoD and its relatives) to the basic helix-loop-helix family, encoded by genes homologous to, and in some cases apparently identical to, the proneural genes that initiate the final phase of development. Their expression is often governed by the Notch pathway via complicated feedback loops.

Terminal cell differentiation has brought us to the end of our sketch of how genes control the making of a fly. Our account necessarily has been simplified. Many more genes than we have mentioned are involved in each of the developmental processes that we have described. Feedback loops, alternative mechanisms operating in parallel, genetic redundancy, and other phenomena complicate the full picture. Despite all this, the overriding message of developmental genetics is one of an unexpected simplicity. A limited number of genes and mechanisms, used repeatedly in different circumstances and combinations, are responsible for controlling the main features of the development of all multicellular animals.

We next turn to an essential aspect of animal development that we have so far neglected: controlled cell movements. [↑ TOP](#)

Summary

The external parts of an adult fly develop from epithelial structures called imaginal discs. Each imaginal disc is divided at the outset into a small number of domains expressing different gene regulatory proteins as a result of early embryonic patterning processes. These domains are called compartments, because their cells do not mix. At the compartment boundaries, cells expressing different genes confront one another and interact, inducing localized production of morphogens that govern the further growth and internal patterning of each compartment. Thus, in the wing disc, dorsal and ventral cells interact by the Notch signaling mechanism to create a source of Wingless (Wnt) protein along the dorsoventral compartment boundary, while anterior and posterior cells interact through short-range Hedgehog signaling to create a source of Dpp protein (a TGF β family member) along the

anteroposterior compartment boundary. All these signaling molecules have homologs that play similar parts in limb patterning in vertebrates.

Within each compartment, the morphogen gradients control the sites of expression of further sets of genes, defining patches of cells that interact with one another yet again to create the finest details of the ultimate pattern of cell differentiation. Thus, proneural gene expression defines the sites where sensory bristles will form, and Notch-mediated interactions among the cells of the proneural cluster, together with asymmetric cell divisions, force the individual cells of the bristle to follow different paths of terminal differentiation.

Each compartment of an imaginal disc, and each substructure within it, grows to a precisely predictable size, even in the face of seemingly drastic disturbances, such as mutations that alter the cell division rate. Although the morphogen gradients in the disc are clearly involved, the critical regulatory mechanisms that control organ size are not understood. [↑ TOP](#)

gene X (open red box) while the maternal chromosome carries a recessive mutant allele (filled red box). Recombination by exchange of DNA between the maternal and paternal chromosomes, catalyzed by the FLP recombinase, can give rise to a pair of daughter cells, one containing two wild-type copies of gene X, the other containing two mutant copies. To help identify the cells where recombination has occurred, the maternal and paternal chromosomes can be chosen to carry, respectively, mutant and wild-type versions of an additional gene that provides a visible marker—a pigmentation gene, for example (not shown here). This marker gene is positioned on the chromosome so that recombination involving the marker locus—resulting in a visible alteration in the appearance of the cells—can be taken as a sure sign that gene X has also undergone recombination.

expressed, GAL4 protein is also made and drives transcription of gene *G*. (B) Although one can achieve the same result by linking a copy of the *H* regulatory sequence directly to the *G* coding sequence, the GAL4/UAS approach allows a strategy that is more efficient in the long run. Two separate "libraries" of transgenic flies are constructed, one containing GAL4 inserts driven by a variety of regulatory sequences of different genes A, B, C, etc., the other containing UAS inserts driving a variety of different coding sequences X, Y, Z, etc. By mating a fly from one library with a fly from the other, any desired coding sequence can be functionally coupled to any desired regulatory sequence. To generate the library of flies with *GAL4* insertions at useful sites, flies are first produced with *GAL4* insertions at random locations in their genome. These are then mated with flies containing a *UAS* element linked to a reporter gene with an easily detectable product. Expression of the reporter reveals whether *GAL4* has been inserted at a site that brings its expression under the control of an interesting enhancer; flies showing interesting reporter patterns are kept and studied. This is called the *enhancer trap* technique, because it provides a way to hunt out and characterize interesting regulatory sequences in the genome.

Figure 21-54. Morphogenetic signals created at compartment boundaries in the wing imaginal disc. (A) Creation of the Dpp signaling region at the anteroposterior compartment boundary through a Hedgehog-mediated interaction between the anterior and posterior cells. In an analogous way, a Notch-mediated interaction between dorsal and ventral cells creates a Wingless (Wnt) signaling region along the dorsoventral boundary. (B) The observed expression patterns of Dpp and Wingless. Although it seems clear that Dpp and Wingless act as morphogens, it is not yet certain whether they spread out from their source by simple diffusion through the extracellular medium or in some other way. Moreover, cells in the imaginal disc have been seen to send out long protrusions, called *cytonemes*, that may allow them to sense signals at a distance. Thus, the receiving cell may send its sensors to the source of the signal, instead of the signal moving to the receiving cell. (B, photographs courtesy of Sean Carroll and Scott Weatherbee, from S.J. Figure 21-59. Lateral inhibition. (A) The basic mechanism of Notch-mediated competitive lateral inhibition, illustrated for just two interacting cells. In this diagram, the absence of color on proteins or effector lines indicates inactivity. (B) The outcome of the same process operating in a larger patch of cells. At first, all cells in the patch are equivalent, expressing both the transmembrane receptor Notch and its transmembrane ligand Delta. Each cell has a tendency to specialize (as a sensory mother cell), and each sends an inhibitory signal to its neighbors to discourage them from also specializing in that way. This creates a competitive situation. As soon as an individual cell gains any advantage in the competition, that advantage becomes magnified. The winning cell, as it becomes more strongly

committed to differentiating as a sensory mother, also inhibits its neighbors more strongly. Conversely, as these neighbors lose their capacity to differentiate as sensory mothers they also lose their capacity to inhibit other cells from doing so. Lateral inhibition thus makes adjacent cells follow different fates. Although the interaction is thought to be normally dependent on cell-cell contacts, the future sensory mother cell may be able to deliver an inhibitory signal to cells that are more than one cell diameter away—for example, by sending out long protrusions to touch them.

Figure 21-60. The result of switching off lateral inhibition during the singling-out of sensory mother cells. The photograph shows part of the thorax of a fly containing a mutant patch in which the neurogenic gene *Delta* has been partially inactivated. The reduction of lateral inhibition has caused almost all the cells in the mutant patch (*in the center of the picture*) to develop as sensory mother cells, producing a great excess of sensory bristles there. Mutant patches of cells carrying more extreme mutations in the Notch pathway, causing a total loss of lateral inhibition, form no visible bristles because all of the progeny of the sensory mother cells develop as neurons or glial cells instead of diversifying to form both neurons and the external parts of the bristle structure. Figure 21-64. Effects of blocking Notch signaling in a *Xenopus* embryo. In the experiment shown, mRNA coding for a truncated form of the Notch ligand Delta is injected, together with *LacZ* mRNA as a marker, into one cell of an embryo at the two-cell stage. The truncated Delta protein produced from the mRNA blocks Notch signaling in the cells descended from the cell that received the injection. These cells lie on the *left* side of the embryo and are identifiable because they contain *LacZ* protein (*blue* stain) as well as the truncated Delta protein. The *right* side of the embryo is unaffected and serves as a control. The embryo is fixed and stained at a stage when the central nervous system has not yet rolled up to form a neural tube, but is still a more or less flat plate of cells—the neural plate—exposed on the surface of the embryo. The first neurons (stained *purple* in the photograph) have already begun to differentiate in elongated bands (proneural regions) on each side of the midline. On the control (*right*) side, they are a scattered subset of the proneural cell population. On the Notch-blocked (*left*) side, virtually all the cells in the proneural regions have differentiated as neurons, creating a densely stained band of neurons without intervening cells. Injections of mRNA coding for normal, functional Delta have an opposite effect, reducing the number of cells that differentiate as neurons. (Photograph from A. Chitnis et al., *Nature* 375:761–766, 1995. © Macmillan Magazines Ltd.)

Cell Movements and the Shaping of the Vertebrate Body

Most cells of the animal body are motile, and in the developing embryo their movements are often extensive, dramatic, and surprising. Controlled changes of gene expression create ordered arrays of cells in different states; cell movements rearrange these cellular building blocks and put them in their proper places. The genes that the cells express determine how they move; in this sense, the control of gene expression is the primary phenomenon. But the cell movements are also crucial, and no less in need of explanation if we want to understand how the architecture of the body is created. In this section, we examine this topic in the context of vertebrate development. We take as our main example the frog *Xenopus laevis* (Figure 21-65), where cell movements have been well studied, though we shall also draw on evidence from chick, zebrafish and mouse.

The Polarity of the Amphibian Embryo Depends on the Polarity of the Egg

The *Xenopus* egg is a large cell, just over a millimeter in diameter (Figure 21-66A). The light-colored lower end of the egg is called the vegetal pole; the dark-colored upper end is called the animal pole. The animal and vegetal hemispheres contain different selections of mRNA molecules and other cell components, which become allocated to separate cells as the egg cell divides after fertilization. Near the vegetal pole, for example, there is an accumulation of mRNAs coding for the gene regulatory protein VegT (a DNA-binding protein of the T-box family) and for signal proteins of the TGF β superfamily, as well as some ready-made protein components of the Wnt signaling pathway (Figure 21-66B). As a result, the cells that inherit vegetal cytoplasm will produce signals to organize the behavior of adjacent cells and are committed to form the gut—the innermost tissue of the body; the cells that inherit animal cytoplasm will form the outer tissues.

Fertilization initiates a complex series of movements that will eventually tuck the vegetal cells and cells from the equatorial (middle) region of the animal-

vegetal axis into the interior. In the process, the three principal axes of the body are established: *anteroposterior*, from head to tail; *dorsoventral*, from back to belly; and *mediolateral*, from the midline outward to the left or to the right. The animal-vegetal asymmetry of the unfertilized egg is sufficient to define only one of these future body axes—the anteroposterior. Fertilization triggers an intracellular movement that gives the egg an additional asymmetry defining a dorsoventral difference. Following entry of the sperm, the outer, actin-rich cortex of the egg cytoplasm rotates relative to the central core of the egg, so that the animal pole of the cortex is slightly shifted to the future ventral side. Treatments that block the rotation allow cleavage to occur normally but produce an embryo with a central gut and no dorsal structures or dorsoventral asymmetry.

The direction of the cortical rotation is biased according to the point of sperm entry, perhaps through the centrosome that the sperm brings into the egg, and the movement is associated with a reorganization of microtubules in the egg cytoplasm. This leads to a microtubule-based transport of the protein Dishevelled, a downstream component of the Wnt signaling pathway, toward the future dorsal side (see [Figure 21-66B](#)). The subcellular region in which Dishevelled thus becomes concentrated gives rise to cells that behave as though they have received a Wnt signal and express a dorsal-specific set of genes as a result. These cells will generate further signals to organize the dorsoventral axis of the body. [↑ TOP](#)

Cleavage Produces Many Cells from One

The cortical rotation is completed in about an hour after fertilization and is followed by cleavage, in which the single large egg cell rapidly subdivides by repeated mitosis into many smaller cells, or *blastomeres*, without any change in total mass ([Figure 21-67](#)). In this way, the determinants distributed asymmetrically in the egg become partitioned into separate cells, with different fates ([Figure 21-68](#)).

These first cell divisions in *Xenopus* have a cycle time of about 30 minutes, with a direct alternation of S and M phases, as discussed in [Chapter 17](#). The very high rate of DNA replication and mitosis seems to preclude gene transcription (although protein synthesis occurs), and the cleaving embryo is almost entirely dependent on reserves of RNA, protein, membrane, and other materials that accumulated in the egg while it developed as an oocyte in the mother. After about 12 cycles of cleavage (7 hours), the cell division rate slows down, the cell cycles begin to follow the standard pattern with G₁ and G₂ phases intervening between the S and M phases, and transcription of the embryo's genome begins. This event is called the *mid-blastula transition*. [↑ TOP](#)

Gastrulation Transforms a Hollow Ball of Cells into a Three-

Layered Structure with a Primitive Gut

During the period of cleavage, the frog embryo becomes transformed from a solid sphere of cells into something more like a hollow ball, with an internal fluid-filled cavity surrounded by cells that cohere to form an epithelial sheet. The embryo is now termed a blastula (Figure 21-69).

Soon after this, the coordinated movements of gastrulation begin. This dramatic process transforms the simple hollow ball of cells into a multilayered structure with a central gut tube and bilateral symmetry: by a more elaborate version of the process outlined earlier for the sea urchin (see Figure 21-3), many of the cells on the outside of the embryo are moved inside it. Subsequent development depends on the interactions of the inner, outer, and middle layers of cells thus formed: the *endoderm* on the inside, consisting of the cells that have moved into the interior to form the primitive gut; the *ectoderm* on the outside, consisting of cells that have remained external; and the *mesoderm* between them, consisting of cells that detach from the epithelium to form a more loosely organized embryonic connective tissue (Figure 21-70). From these three *germ layers*, the tissues of the adult vertebrate body will be generated, preserving the basic body plan established through gastrulation. [↑ TOP](#)

The Movements of Gastrulation Are Precisely Predictable

The pattern of gastrulation movements that creates the germ layers and establishes the body axes is described for *Xenopus* in Figure 21-71. The details are complex, but the principles are simple.

Cells of the future endoderm are folded into the interior, or *involted*, in succession. The cells that were near the vegetal pole of the blastula involute first, turning inward and then moving up toward the animal pole to form the most anterior part of the gut. As they near the animal pole, these leading endoderm cells will signal to the overlying ectoderm to define the anterior extremity of the head. The mouth will eventually develop as a hole formed at an anterior site where endoderm and ectoderm come into direct contact. Meanwhile, future mesoderm cells, destined to detach from the epithelial sheet to form the sandwich filling between endoderm and ectoderm, tuck into the interior along with the endoderm cells, and also move up toward the animal pole. The cells that are first to involute go to form parts of the head, and those that are last form parts of the tail. In this way, the anteroposterior axis of the final embryo is laid down sequentially.

The anteroposterior movements go hand in hand with movements that organize the dorsoventral axis of the body. Gastrulation begins on the side of the blastula that has been marked out as dorsal by the cortical rotation. Here, involution of cells into the interior starts with a short indentation that rapidly extends to form the *blastopore*—a line of invagination that curves around to

encircle the vegetal pole. The site where the invagination starts defines the *dorsal lip of the blastopore*. As we shall see, this tissue plays a leading part in subsequent events and gives rise to the central dorsal structures of the main body axis. [↑ TOP](#)

Chemical Signals Trigger the Mechanical Processes

The movements of gastrulation are triggered by chemical signals from the vegetal blastomeres. Several proteins of the TGF β superfamily are secreted by these cells and act on the blastomeres above them. If these signals are blocked, gastrulation is disrupted and no mesodermal cell types are generated. The local activation of components of the Wnt signaling pathway on the dorsal side of the embryo (as a result of the earlier cortical rotation, see [Figure 21-66](#)) modifies the action of the other signals so as to induce development of the special cells that form the dorsal lip of the blastopore ([Figure 21-72](#)).

The dorsal lip of the blastopore plays a central role in gastrulation not just in a geometrical sense, but as a powerful new source of control. If the dorsal lip of the blastopore is excised from an embryo at the beginning of gastrulation and grafted into another embryo but in a different position, the host embryo initiates gastrulation both at the site of its own dorsal lip and at the site of the graft. The movements of gastrulation at the second site entail the formation of a second whole set of body structures, and a double embryo (Siamese twins) results (see [Figure 21-6B](#)).

Evidently, the dorsal lip of the blastopore is the source of a signal (or signals) coordinating both the movements of gastrulation and the pattern of specialization of the tissues in its neighborhood. Because of this crucial role in organizing the formation of the main body axis, the dorsal lip of the blastopore is known as the **Organizer** (or Spemann's Organizer, after its co-discoverer). It is the oldest and most famous example of an *embryonic signaling center*. [↑ TOP](#)

Active Changes of Cell Packing Provide a Driving Force for Gastrulation

The Organizer controls the dorsoventral pattern of cell differentiation in its neighborhood by secreting proteins, including chordin that inhibit the action of the TGF β -like signals (specifically BMP proteins) produced by the more ventral cells ([Figure 21-72C](#)). This sets up a gradient of signaling activity—a morphogen gradient, whose local value tells cells how far they lie from the Organizer (see [Figure 21-14](#)). But how is the pattern of cell movements organized in mechanical terms, and what are the forces that bring it about?

Gastrulation begins with changes in the shape of the cells at the site of the blastopore. In the amphibian these are called bottle cells: they have broad

bodies and narrow necks that anchor them to the surface of the epithelium (Figure 21-73), and they may help to force the epithelium to curve and so to tuck inward, producing the initial indentation seen from outside. Once this first tuck has formed, cells can continue to pass into the interior as a sheet to form the gut and mesoderm. The movement seems to be driven mainly by an active repacking of the cells, especially those in the involuting regions around the Organizer (see Figure 21-73). Here convergent extension occurs. Small square fragments of tissue from these regions, isolated in culture, will spontaneously narrow and elongate through a rearrangement of the cells, just as they would in the embryo in the process of converging toward the dorsal midline, turning inward around the blastopore lip, and then elongating to form the main axis of the body.

To bring about this remarkable transformation, the individual cells have to crawl over one another in a coordinated way (Figure 21-74). The alignment of their movements appears to depend on the same machinery we encountered in the worm and the fly controlling planar cell polarity: the Frizzled/Dishevelled polarity-signaling pathway. When this pathway is blocked—for example, by a dominant-negative form of Dishevelled—convergent extension fails to occur.  [TOP](#)

Changing Patterns of Cell Adhesion Molecules Force Cells Into New Arrangements

Patterns of gene expression govern embryonic cell movements in many different ways. They regulate cell motility, cell shape, and the production of signals for guidance. Very importantly, they also determine the sets of adhesion molecules that the cells display on their surfaces. Through changes in its surface molecules, a cell can break old attachments and make new ones. Cells in one region may develop surface properties that make them cohere with one another and become segregated from a neighboring group of cells whose surface chemistry is different.

Experiments done half a century ago on early amphibian embryos showed that the effects of selective cell-cell adhesion can be so powerful that they can bring about an approximate reconstruction of the normal structure of an early postgastrulation embryo even after the cells have been artificially dissociated. When these cells are reaggregated into a random mixture, the cells sort out spontaneously according to their original characters (Figure 21-75). As discussed in Chapter 19, a central role in such phenomena is played by the *cadherins*—a large and varied family of evolutionarily related Ca^{2+} -dependent cell-cell adhesion proteins. These and other cell-cell-adhesion molecules are differentially expressed in the various tissues of the early embryo, and antibodies against them interfere with the normal selective adhesion between cells of a similar type.

Changes in the patterns of expression of the various cadherins correlate closely

with the changing patterns of association among cells during gastrulation, neurulation, and somite formation (see [Figure 19-25](#)). These rearrangements are likely to be regulated and driven in part by the cadherin pattern. In particular, cadherins appear to have a major role in controlling the formation and dissolution of epithelial sheets and clusters of cells. They not only glue one cell to another, but also provide anchorage for intracellular actin filaments at the sites of cell-cell adhesion. In this way the pattern of stresses and movements in the developing tissue is regulated according to the pattern of adhesions. [↑ TOP](#)

The Notochord Elongates, While the Neural Plate Rolls Up to Form the Neural Tube

Gastrulation is only the first—though perhaps the most dramatic—of a dizzying variety of cell movements that shape the parts of the body. We have space to discuss only a few of these.

In the embryo just after gastrulation, the layer of mesoderm is divided into separate slabs on the left and right sides of the body. Defining the central body axis, and effecting this separation, is the very early specialization of the mesoderm known as the notochord. This slender rod of cells, with ectoderm above it, endoderm below it, and mesoderm on either side (see [Figure 21-70](#)), derives from the cells of the Organizer itself. The notochordal cells are characterized by expression of a gene regulatory protein called Brachyury (Greek for "short-tail", from the mutant phenotype); this belongs to the same T-box family as the VegT protein in the vegetal blastomeres.

As the notochordal cells pass around the dorsal lip of the blastopore and move into the interior of the embryo, they form a column of tissue that elongates dramatically by convergent extension. The cells of the notochord also become swollen with vacuoles, so that the rod elongates still further and stretches out the embryo. The notochord is the defining peculiarity of the chordates—the phylum to which the vertebrates belong. It is one of the major vertebrate features that do not have any apparent counterpart in *Drosophila*. In the most primitive chordates, which have no vertebrae, the notochord persists as a primitive substitute for a vertebral column. In vertebrates it serves as a core around which other mesodermal cells will eventually gather to form the vertebrae.

In the overlying sheet of ectoderm, meanwhile, other movements are occurring to form the rudiments of the nervous system. In a process known as *neurulation*, a broad central region of ectoderm, called the *neural plate*, thickens, rolls up into a tube, and pinches off from the rest of the cell sheet. The tube thus created from the ectoderm is called the neural tube; it will form the brain and the spinal cord ([Figure 21-76](#)).

The mechanics of neurulation depend on changes of cell packing and cell

shape that make the epithelium roll up into a tube (Figure 21-77). Signals initially from the Organizer and later from the underlying notochord and mesoderm define the extent of the neural plate, induce the movements that make it roll up, and help to organize the internal pattern of the neural tube. The notochord in particular secretes Sonic hedgehog protein—a homolog of the *Drosophila* signal protein Hedgehog—and this acts as a morphogen to control gene expression in the neighboring tissues (see Figure 21-94). [↑ TOP](#)

A Gene-Expression Oscillator Controls Segmentation of the Mesoderm Into Somites

Genetically regulated changes in cell adhesion underlie one of the most striking and characteristic processes in vertebrate development—the formation of the segments of the body axis.

On either side of the newly formed neural tube lies a slab of mesoderm (see Figure 21-70). To form the repetitive series of vertebrae, ribs, and segmental muscles, this slab breaks up into separate blocks, or somites—cohesive groups of cells, separated by clefts. Figure 21-78A shows the process as it occurs in the chick embryo. The somites form one after another, starting in the head and ending in the tail. Depending on the species, the final number of somites ranges from less than 50 (in a frog or a bird) to more than 300 (in a snake). The posterior, most immature part of the mesodermal slab, called the *presomitic mesoderm*, supplies the necessary tissue: as it retreats tailward, extending the embryo, it deposits a trail of somites.

Formation of the cleft between one somite and the next is foreshadowed by an alternating spatial pattern of gene expression in the presomitic mesoderm: cells about to form the posterior part of a new somite switch on expression of one set of genes, while those destined to form the anterior part of the next somite switch on expression of another set. The genes that mark out the somite pattern in this way include at least one member of the cadherin superfamily (called *paraxial protocadherin*), and the intersomitic cleft forms where cells that express it confront cells that do not. Selective cohesion resulting from differential gene expression (either of this gene or some other) thus seems to be the underlying cause of the physical segmentation observed.

The problem then is to understand how the repetitive alternating pattern of gene expression is set up. Studies in the chick embryo have provided an answer. In the posterior part of the presomitic mesoderm, expression of certain genes—in particular the gene *c-hairy-1*, a homolog of the *Drosophila* pair-rule gene *hairy*—is found to oscillate in time. The length of one complete oscillation cycle of this gene-expression "clock" (90 minutes in the chick) equals the time taken to lay down one further somite. As cells mature and emerge from the presomitic mesoderm to form somites, their oscillation is arrested. *c-hairy-1* encodes a gene regulatory protein, and the cells arrested at the peak of their *c-hairy-1* oscillation cycle express one set of genes, while

those arrested at the trough of the cycle express another (Figure 21-78B). In this way, the temporal oscillation of gene expression in the presomitic mesoderm leaves its trace in a spatially periodic pattern of gene expression in the maturing mesoderm, and this in turn dictates how the tissue will break up into physically separate blocks. The mechanism that generates the temporal oscillation itself is unknown.

Most of the cells of each newly formed somite will rapidly differentiate to form a block of muscle, corresponding to one muscle segment of the main body axis. The embryo can (and does) now begin to wriggle. Separate subsets of the somite cells will go to form the vertebrae and other connective tissues such as dermis. A further subset detach from the somite and migrate away into the lateral unsegmented mesoderm, crawling through the spaces between other cells: these emigrants will give rise to almost all the other skeletal muscle cells in the body, including those of the limbs. [↑ TOP](#)

Embryonic Tissues Are Invaded in a Strictly Controlled Fashion by Migratory Cells

The muscle-cell precursors, or *myoblasts*, that emigrate from the somites are determined but not overtly differentiated. In the tissues that they colonize they will mingle with other classes of cells from which they appear practically indistinguishable; but they will maintain expression of myoblast-specific gene regulatory proteins (such as members of the MyoD family), and when the time comes for differentiation, they, and they alone, will turn into muscle cells (Figure 21-79).

The eventual pattern of muscles—in the limbs, for example—is determined by the routes that the migrant cells follow and the selection of sites that they colonize. The embryonic connective tissues form the framework through which the myoblasts travel and provide signals that guide their distribution. No matter which somite they come from, myoblasts that migrate into a forelimb bud will form the pattern of muscles appropriate to a forelimb, and those that migrate into a hindlimb bud will form the pattern appropriate to a hindlimb.

Other classes of migrant cells, meanwhile, select different routes for their travels. Along the line where the neural tube pinches off from the future epidermis, a number of ectodermal cells break loose from the epithelium and also migrate as individuals out through the mesoderm (Figure 21-80). These are the cells of the **neural crest**; they will give rise to almost all of the neurons and glial cells of the peripheral nervous system, as well as the pigment cells of the skin and many connective tissues in the head, including bones of the skull and jaws. Other important migrants are the precursors of the blood cells, of the germ cells, and of many groups of neurons within the central nervous system, as well as the *endothelial cells* that form blood vessels. Each of these classes of travelers will colonize a different set of sites. As a result of such invasions, most tissues in the vertebrate body are mixtures of cells of different characters

derived from widely separate parts of the embryo.

As a migrant cell travels through the embryonic tissues, it repeatedly extends projections that probe its immediate surroundings, testing for subtle cues to which it is particularly sensitive by virtue of its specific assortment of cell-surface receptor proteins. Inside the cell these receptor proteins are connected to the cytoskeleton, which moves the cell along. Some extracellular matrix materials, such as the protein fibronectin, provide adhesive sites that help the cell to advance; others, such as chondroitin sulfate proteoglycan, inhibit locomotion and repel immigration. The nonmigrant cells along the pathway may likewise have inviting or repellent surfaces, or may even extend filopodia that touch the migrant cell and affect its behavior. An incessant tug-of-war between opposing tentative attachments made by the migrant cell leads to a net movement in the most favored direction until the cell finds a site where it can form a lasting attachment. Other factors such as chemotaxis and interactions among the migratory cells may also contribute to their guidance. [↑ TOP](#)

The Distribution of Migrant Cells Depends on Survival Factors as Well as Guidance Cues

The final distribution of migrant cells depends not only on the routes they take, but also on whether they survive the journey and thrive in the environment they find at the journey's end. Specific sites provide survival factors needed by specific types of migrant. For example, the neural crest cells that give rise to the pigment cells of the skin and the nerve cells of the gut depend on a peptide factor called *Endothelin-3* that is secreted by tissues on the migration pathways; mutant mice and humans defective in the gene for this factor or its receptor have non-pigmented (albino) patches and potentially lethal gut malformations resulting from the lack of gut innervation (a condition called megacolon, because the colon becomes hugely distended).

Germ cells, blood cell precursors, and neural-crest-derived pigment cells all appear to share at least one common requirement for survival. This involves a transmembrane receptor, called the *Kit protein*, in the membrane of the migrant cells and a ligand, called the *Steel factor*, produced by the cells of the tissue through which the cells migrate and/or in which they come to settle. Individuals with mutations in the genes for either of these proteins are deficient in their pigmentation, their supply of blood cells, and their production of germ cells ([Figure 21-81](#)). [↑ TOP](#)

Left-Right Asymmetry of the Vertebrate Body Derives From Molecular Asymmetry in the Early Embryo

Vertebrates may look bilaterally symmetrical from the outside, but many of their internal organs—the heart, the stomach, the liver, and so on—are highly asymmetric. This asymmetry is quite reproducible: 99.98% of people have

their heart on the left. We have seen how a vertebrate embryo develops its internal and external tissue layers and its anteroposterior and dorsoventral axes. But how does the left-right asymmetry arise?

Genetic studies in mammals show that this problem can be broken down into two distinct questions—one concerning the creation of asymmetry and the other concerning its orientation. Several mutations are known, in humans and in mice, that cause a randomization of the left-right axis: 50% of the mutant individuals have their internal organs arranged in the normal way, while the other 50% have an inverted anatomy, with the heart on the right. In these individuals, it seems, the mechanism that makes the left and right sides different has functioned correctly, but the mechanism that decides between the two possible orientations of the left-right axis is defective.

A key to the basis of these phenomena comes from the discovery of molecular asymmetries that precede the first gross anatomical asymmetries. The earliest signs are seen in patterns of gene expression in the neighborhood of the *node*—the homolog in mouse and chick of the frog Organizer. Several members of the TGF β superfamily are expressed asymmetrically in this region (not only in the mouse, but also in chick, frog and zebrafish), as are some other signal proteins including Sonic hedgehog (Figure 21-82). These factors regulate one another's production, producing a cascade of effects through which an asymmetry in the immediate neighborhood of the node apparently becomes self-reinforcing and is relayed outward to create an asymmetric pattern of gene expression over a much larger region.

Mutations in some of these signaling components can have the effect of obliterating the asymmetry, so as to give a mirror-symmetrical anatomy. For example, mice with a knock-out mutation in the *Lefty-1* gene (coding for a Tgf β -superfamily member) frequently have the right side converted into a mirror image of the left. The mechanism that normally forces the two sides to be different is still not understood. Somehow, cells neighboring the node on opposite sides must become different even if there is very little difference between them at the outset. One possibility is that some sort of lateral inhibition operates: cells on opposite sides of the node may exchange mutually inhibitory signals, and thereby compete with one another to adopt a left-side (or a right-side) character. Or perhaps some small but influential group of cells, originating near the midline, is forced to one side by the formation of other midline structures.

Whatever the mechanism, the outcome of events at the node in a normal animal must be biased so that left-specific genes are regularly expressed on the left side: there has to be a link between the mechanism that creates asymmetry and the mechanism that orients it. A clue to the orienting mechanism first came to light in a Swedish infertility clinic. A small subset of infertile men were found to have sperm that were immotile because of a defect in the dynein molecules needed for beating of cilia and flagella. These men also suffered from chronic bronchitis and sinusitis because the cilia in their respiratory tract

were defective. And strikingly, 50% of them had their internal organs left-right inverted, with the heart on the right. The findings originally seemed completely mysterious; but similar effects are seen in mammals with other mutations resulting in defective cilia. This suggests that ciliary beating somehow controls which way the left-right axis is oriented.

Time-lapse videomicroscopy in the living mouse embryo reveals that the cells at the node, on its internal face, have cilia that beat in a helical fashion: like a screw-thread, they have a definite handedness, and at the node they are set in a little hollow that is shaped so that their beating drives a current of fluid towards the left side (see [Figure 21-82A](#)). Signal proteins carried in this current are thought to provide the bias that orients the left-right axis of the mouse body.

The handedness of the ciliary beating reflects the handedness—the left-right asymmetry—of the organic molecules of which all living things are made. It seems that this, therefore, is the ultimate director of the left-right asymmetry of our anatomy. [↑ TOP](#)

Summary

Animal development involves dramatic cell movements. Thus, in gastrulation, cells from the exterior of the early embryo tuck into the interior to form a gut cavity and create the three germ layers—endoderm, mesoderm, and ectoderm—from which higher animals are constructed. In vertebrates, the movements of gastrulation are organized by signals from the Organizer (the dorsal lip of the amphibian blastopore, corresponding to the node in a chick or mouse embryo). These signals specify the dorsoventral axis of the body and govern convergent extension, in which the sheet of cells moving into the interior of the body lengthens along the head-to-tail axis while narrowing at right angles to this axis. The active repacking movements of individual cells that drive convergent extension are coordinated through the Frizzled/Dishevelled planar-polarity signaling pathway—a branch of the Wnt signaling pathway that regulates the actin cytoskeleton.

Subsequent development involves many further cell movements. Part of the ectoderm thickens, rolls up, and pinches off to form the neural tube and neural crest. In the midline, a rod of specialized cells called the notochord elongates to form the central axis of the embryo. The long slabs of mesoderm on either side of the notochord become segmented into somites. Migrant cells, such as those of the neural crest, break loose from their original neighbors and travel through the embryo to colonize new sites. Specific cell-adhesion molecules, such as cadherins and integrins, help to guide the migrations and control the selective cohesion of cells in new arrangements.

Ultimately, the pattern of cell movements is directed by the pattern of gene expression, which determines cell surface properties and motility. Thus, the

formation of somites depends on a periodic pattern of gene expression, which is laid down by a biochemical oscillator in the mesoderm and dictates the way the mass of cells will break up into separate blocks. Similarly, the left-right anatomical asymmetry of the vertebrate body is foreshadowed by left-right asymmetry in the pattern of gene expression in the early embryo. This asymmetry, in mammals at least, is thought to be directed ultimately by the handedness of ciliary beating in the neighborhood of the node. [↑ TOP](#)

Figure 21-68. The origins of the three germ layers can be traced back to distinct blastomeres of the embryo in its early cleavage stages. The endoderm derives from the most vegetal blastomeres, the ectoderm from the most animal, and the mesoderm from a middle set that contribute also to endoderm and ectoderm. The coloring in each picture is the more intense, the higher the proportion of cell progeny that will contribute to the given germ layer. (After L. Dale, *Curr. Biol.* 9:R812–R815, 1999.)

Figure 21-69. The blastula. In the outermost regions of the embryo, tight junctions between the blastomeres begin to create an epithelial sheet that isolates the interior of the embryo from the external medium. Na^+ is pumped across this sheet into the spaces in the interior of the embryo, and water follows into these spaces because of the resulting osmotic pressure gradient. As a result, the intercellular crevices inside the embryo enlarge to form a single cavity, the *blastocoel*. In *Xenopus* the wall of the blastocoel is several cells thick, and only the outermost cells are tightly bound together as an epithelium.

Development of Multicellular Organisms → Cell Movements and the Shaping of the Vertebrate Body

Figure 21-70. A cross section through the trunk of an amphibian embryo after the end of gastrulation, showing the arrangement of endodermal, mesodermal and ectodermal tissues.

The endoderm will form the epithelial lining of the gut, from the mouth to the anus. It gives rise not only to the pharynx, esophagus, stomach, and intestines, but also to many associated glands. The salivary glands, the liver, the pancreas, the trachea, and the lungs, for example, all develop from extensions of the wall of the originally simple digestive tract and grow to become systems of branching tubes that open into the gut or pharynx. The endoderm forms only the epithelial components of these structures—the lining of the gut and the secretory cells of the pancreas, for example. The supporting muscular and fibrous elements arise from the mesoderm. The mesoderm gives rise to the connective tissues—at first to the loose, space-filling, three-dimensional mesh of cells in the embryo known as mesenchyme and ultimately to cartilage, bone, and fibrous tissue, including the dermis (the inner layer of the skin). The mesoderm also forms the muscles, the entire vascular system—including the heart, the blood vessels, and the blood cells—and the tubules, ducts, and supporting tissues of the kidneys and gonads. The ectoderm will form the epidermis (the outer, epithelial layer of the skin) and epidermal appendages such as hair, sweat glands, and mammary glands. It will also give rise to the whole of the nervous system, central and peripheral, including not only neurons and glia but also the sensory cells of the nose, the ear, the eye, and other sense organs. (After T. Mohun et al., *Cell* 22:9–15, 1980.)

from the side; with the directions of cell movement indicated by *red arrows*, cross sections (*below*) are cut in the median plane (the plane of the dorsal and ventral midlines). Gastrulation begins when a short indentation, the beginning of the blastopore, becomes visible in the exterior of the blastula. This indentation gradually extends, curving around to form a complete circle surrounding a plug of very yolky cells (destined to be enclosed in the gut and digested). Sheets of cells meanwhile turn in around the lip of the blastopore and move deep into the interior of the embryo. At the same time the external epithelium in the region of the animal pole actively spreads to take the place of the cell sheets that have turned inward. Eventually, the epithelium of the animal hemisphere spreads in this way to cover the whole external surface of the embryo, and, as gastrulation reaches completion, the blastopore circle shrinks almost to a point. (B) A fate map for the early *Xenopus* embryo (viewed from the side) as it begins gastrulation, showing the origins of the cells that will come to form the three germ layers as a result of the movements of gastrulation. The various parts of the mesoderm (lateral plate, somites, and notochord) derive from deep-lying cells that segregate from the epithelium in the cross-hatched region. The other cells, including the more superficial cells in the cross-hatched region, will give rise to ectoderm (*blue, above*) or endoderm (*yellow, below*). Roughly speaking, the first cells to turn into the interior, or *involute*, will move forward inside the embryo to form the most anterior endodermal and mesodermal structures, while the last to involute will form the most posterior structures. (C) Cartoon to show how the different regions of the ectoderm map into the body surface of the adult animal. (After R.E. Keller, *J. Exp. Zool.* 216:81–101, 1981 and *Dev. Biol.* 42:222–241, 1975.)

Figure 21-73. Cell movements in gastrulation. A section through a gastrulating *Xenopus* embryo, cut in the same plane as in Figure 21-71, indicating the four main types of movement that gastrulation involves. The animal pole epithelium expands by cell rearrangement, becoming thinner as it spreads. Migration of mesodermal cells over a fibronectin-rich matrix lining the roof of the blastocoel may help to pull the invaginated tissues forward. But the main driving force for gastrulation in *Xenopus* is convergent extension in the marginal zone. (After R.E. Keller, *J. Exp. Zool.* 216:81–101, 1981.)

Figure 21-74. Convergent extension and its cellular basis. (A) The pattern of convergent extension in the marginal zone of a gastrula as viewed from the dorsal aspect. *Blue arrows* represent convergence toward the dorsal midline, *red arrows* represent extension of the anteroposterior axis. The simplified diagram does not attempt to show the accompanying movement of involution, whereby the cells are tucking into the interior of the embryo. (B) Schematic diagram of the cell behavior that underlies convergent extension. The cells form lamellipodia, with which they attempt to crawl over one another. Alignment of the lamellipodial movements along a common axis leads to convergent extension. The process depends on the Frizzled/Dishevelled polarity-signaling pathway and is presumably cooperative because cells that are already aligned exert forces that tend to align their neighbors in the same way. (B, after J. Shih and R. Keller, *Development* 116:901–914, 1992.)

Figure 21-78. Somite formation in the chick embryo. (A) A chick embryo at 40 hours of incubation. (B) How the temporal oscillation of *c-hairy-1* expression in the presomitic mesoderm becomes converted into a spatial pattern of gene expression in the formed somites. In the posterior part of the presomitic mesoderm, each cell oscillates with a cycle time of 90 minutes. As cells mature and emerge from the presomitic region, their oscillation is gradually slowed down and finally brought to a halt in whatever phase of the cycle they happen to be in at the critical moment. In this way, a temporal oscillation of gene expression traces out an alternating spatial pattern. (A, from Y.J. Jiang, L. Smithers and J. Lewis, *Curr. Biol.* 8:868–871, 1998. © Elsevier.)

Figure 21-79. The migratory origin of limb muscle cells. The migrations can be traced by grafting cells from a quail embryo into a chick embryo; the two species are very similar in their development, but the quail cells are recognizable by the distinctive appearance of their nucleoli. If quail somite cells are substituted for the somite cells of a chick embryo at 2 days of incubation and the wing of the chick is sectioned a week later, it is found that the muscle cells in the chick wing derive from the transplanted quail somites.

Figure 21-80. The main pathways of neural crest cell migration. A chick embryo is shown in a schematic cross-section through the middle part of the trunk. The cells that take the pathway just beneath the ectoderm will form pigment cells of the skin; those that take the deep pathway via the somites will form the neurons and glial cells of sensory and sympathetic ganglia, and parts of the adrenal gland. The neurons and glial cells of the enteric ganglia, in the wall of the gut, are formed from neural crest cells that migrate along the length of the body, originating from either the neck region or the sacral region. In *Drosophila*, neurons in the wall of the gut originate in a similar way, by migration from the head end of the embryo. (See also [Figure 19-23](#).)

Development of Multicellular Organisms

The Mouse

The mouse embryo—tiny and inaccessible in its mother's womb—presents a hard challenge to developmental biologists. It has, however, two immediate attractions. First, the mouse is a mammal, and mammals are the animals that we, as humans, care about most. Second, among mammals, it is one of the most convenient for genetic studies, because it is small and breeds rapidly. These two factors have spurred an enormous research effort, resulting in the development of some remarkably powerful experimental tools. In this way, the mouse has become the main model organism for experimentation in mammalian genetics and the most intensively studied surrogate for humans. It is separated from humans by only about 100 million years of evolution. Its genome is the same as ours in size, and there is very nearly a one-to-one correspondence between mouse and human genes. Our proteins are typically 80–90% identical in amino-acid sequence, and large blocks of close nucleotide sequence similarity are also evident when the regulatory DNA sequences are compared.

Through ingenuity and perseverance, developmental biologists have now found ways to gain access to the early mouse embryo without killing it and to generate mice to order with mutations in any chosen gene. Almost any genetic modification that can be made in a worm, a fly, or a zebrafish can now also be made in the mouse, and in some cases made better. The costs of research in the mouse are far greater, but so are the incentives. As a result, the mouse has become a rich source of information about all aspects of the molecular genetics of development—a key model system not only for mammals, but also for other animals. It has provided, for example, much of what we know about Hox genes, left-right asymmetry, cell death controls, the role of Notch signaling, and a host of other topics.

We have already drawn repeatedly upon data from the mouse. We shall make use of it even more in the next chapter, where we discuss adult tissues and the developmental processes that occur in them. In this section, we examine the special features of mouse development that have been exploited to make the genetic manipulations possible. By way of example, we shall also outline how the mouse has been used to illuminate one further important developmental process—the creation of organs such as lungs and glands by interactions

between embryonic connective tissue and epithelium.

Mammalian Development Begins With a Specialized Preamble

The mammalian embryo begins its development in an exceptional way. Protected within the uterus, it does not have the same need as the embryos of most other species to complete the early stages of development rapidly. Moreover, the development of a placenta quickly provides nutrition from the mother, so that the egg does not have to contain large stores of raw materials such as yolk. The egg of a mouse has a diameter of only about 80 μm and therefore a volume about 2000 times smaller than that of a typical amphibian egg. Its cleavage divisions occur no more quickly than the divisions of many ordinary somatic cells, and gene transcription has already begun by the two-cell stage. Most importantly, while the later stages of mammalian development are similar to those of other vertebrates such as *Xenopus*, mammals begin by taking a large developmental detour to generate a complicated set of structures—notably the amniotic sac and the placenta—that enclose and protect the embryo proper and provide for the exchange of metabolites with the mother. These structures, like the rest of the body, derive from the fertilized egg but are called *extraembryonic* because they are discarded at birth and form no part of the adult. Similar accessory structures are formed in the development of birds and reptiles.

The early stages of mouse development are summarized in [Figure 21-83](#). The fertilized egg divides to generate 16 cells by three days after fertilization. At first, the cells stick together only loosely, but at the 16-cell stage they become more cohesive and undergo *compaction* to form a solid ball of cells called a *morula* (Latin for "little mulberry") ([Figure 21-84](#)). Tight junctions form between the cells, sealing off the interior of the morula from the external medium. Soon after this, an internal cavity develops, converting the morula into a *blastocyst*—a hollow sphere. The outer layer of cells, forming the wall of the sphere, is called the *trophectoderm*. It will give rise to extraembryonic tissues. An inner clump of cells, called the *inner cell mass*, is located to one side of the cavity. It will give rise to the whole of the embryo proper.

After the embryo has escaped from its jelly capsule (at about four days), the cells of the trophectoderm make close contact with the wall of the uterus, initiating formation of the placenta. Meanwhile the inner cell mass grows and begins to differentiate. Part of it gives rise to some further extraembryonic structures, such as the yolk sac, while the rest of it goes on to form the embryo proper by processes of gastrulation, neurulation, and so on, that are fundamentally similar to those seen in other vertebrates, although distortions of the geometry make some of the homologies hard to discern at first sight. [↑ TOP](#)

The Early Mammalian Embryo Is Highly Regulative

Localized intracellular determinants play only a small part in early mammalian development, and the blastomeres produced by the first few cell divisions are remarkably adaptable. If the early embryo is split in two, a pair of identical twins can be produced—two complete normal individuals from a single cell. Similarly, if one of the cells in a two-cell mouse embryo is destroyed by pricking it with a needle and the resulting "half-embryo" is placed in the uterus of a foster mother to develop, in many cases a perfectly normal mouse will emerge.

Conversely, two eight-cell mouse embryos can be combined to form a single giant morula, which then develops into a mouse of normal size and structure (Figure 21-85). Such creatures, formed from aggregates of genetically different groups of cells, are called *chimeras*. Chimeras can also be made by injecting cells from an early embryo of one genotype into a blastocyst of another genotype. The injected cells become incorporated into the inner cell mass of the host blastocyst, and a chimeric animal develops. A single injected cell taken from an eight-cell embryo or from the inner cell mass of another early blastocyst can give rise to any combination of cell types in the chimera. Wherever the injected cell may happen to find itself, it responds correctly to cues from its neighbors and follows the appropriate developmental pathway.

These findings have two implications. First, during the early stages, the developmental system is self-adjusting, so that a normal structure emerges even if the starting conditions are perturbed. Embryos or parts of embryos that have this property are said to be **regulative**. Second, the individual cells of the inner cell mass are initially *totipotent*: they can give rise to any part of the adult body, including germ cells.  [TOP](#)

Totipotent Embryonic Stem Cells Can Be Obtained From a Mammalian Embryo

If a normal early mouse embryo is grafted into the kidney or testis of an adult, its development is disturbed beyond any possibility of proper regulation, but not halted. The result is a bizarre tumorous growth known as a *teratoma*, consisting of a disorganized mass of cells containing many varieties of differentiated tissue—skin, bone, glandular epithelium, and so on—mixed with undifferentiated stem cells that continue to divide and generate yet more of these differentiated tissues.

Investigation of the stem cells in teratomas and related types of tumors led to the discovery that their behavior reflects a remarkable property of the cells of the normal inner cell mass: given a suitable environment, they can be induced to proliferate indefinitely while retaining their totipotent character. Cultured cells with this property are called embryonic stem cells, or **ES cells**. They can be derived by placing a normal inner cell mass in culture and dispersing the cells as soon as they proliferate. Separating the cells from their normal neighbors and putting them in the appropriate culture medium evidently arrests

the normal program of change of cell character with time and so enables the cells to carry on dividing indefinitely without differentiating. Many tissues of the adult body also contain stem cells that can divide indefinitely without terminally differentiating, as we shall see in the next chapter; but these *adult stem cells*, when allowed to differentiate, normally give rise only to a narrowly restricted range of differentiated cell types.

The state in which the ES cells are arrested seems to be equivalent to that of normal inner-cell-mass cells. This can be shown by taking ES cells from the culture dish and injecting them into a normal blastocyst ([Figure 21-86](#)). The injected cells become incorporated in the inner cell mass of the blastocyst and can contribute to the formation of an apparently normal chimeric mouse. Descendants of the injected stem cells can be found in practically any of the tissues of this mouse, where they differentiate in a well-behaved manner appropriate to their location and can even form viable germ cells. The extraordinarily adaptable behavior of ES cells shows that cues from a cell's neighbors not only guide choices between different pathways of differentiation, but can also stop or start the developmental clock—the processes that drive a cell to progress from an embryonic to an adult state.

On a practical level, ES cells have a two-fold importance. First, from a medical point of view, they offer the prospect of a versatile source of cells for repair of damaged and defective tissues in the adult body, as we shall discuss at the end of the next chapter. Second, ES cells make possible the most precisely controlled forms of genetic modification, allowing animals to be created with virtually any desired alteration introduced into their genome. The technique uses genetic recombination to substitute an artificially constructed DNA segment for the normal DNA sequence at a chosen site in the genome of an ES cell. Although only a rare cell incorporates the DNA construct correctly, selection procedures have been devised to find this cell among the thousands of cells into which the DNA construct has been transfected. Once selected, the genetically modified ES cells can be injected into a blastocyst to make a chimeric mouse. This mouse will, with luck, have some ES-derived germ cells, capable of acting as founders of a new generation of mice that consist entirely of cells carrying the carefully designed mutation. In this way, an entire mutant mouse can be resurrected from the culture dish (see [Figure 8-70](#)). [↑ TOP](#)

Interactions Between Epithelium and Mesenchyme Generate Branching Tubular Structures

Vertebrates are comparatively big animals, and they owe much of their bulk to connective tissues. For excretion, absorption of nutrients, and gas exchange, however, they also require large quantities of various specialized types of epithelial surfaces. Many of these take the form of tubular structures created by *branching morphogenesis*, in which an epithelium invades embryonic connective tissue (mesenchyme) to form a composite organ. The lung is a typical example. It originates from the endoderm lining the floor of the

foregut. This epithelium buds and grows out into the neighboring mesenchyme to form the *bronchial tree*, a system of tubes that branch repeatedly as they extend ([Figure 21-87](#)). The same mesenchyme is also invaded by endothelial cells—the lining cells of blood vessels—to create the system of closely apposed airways and blood vessels required for gas exchange in the lung (discussed in [Chapter 22](#)).

The whole process depends on exchanges of signals in both directions between the growing buds of epithelium and the mesenchyme that they are invading. These signals can be analyzed by genetic manipulation in the mouse. A central part is played by signal proteins of the fibroblast growth factor (FGF) family and the receptor tyrosine kinases on which they act. This signaling pathway has various roles in development, but it seems to be especially important in the many interactions that occur between epithelium and mesenchyme.

Mammals have about 20 different FGF genes, as compared with just one in *Drosophila* and in *C. elegans*. The FGF that is most important in the lung is FGF10. This is expressed in clusters of mesenchyme cells near the tips of the growing epithelial tubes, while its receptor is expressed in the epithelial cells themselves. FGF10 or its receptor can be knocked out (by the standard techniques based on recombination in ES cells). In the resulting knock-out mutant mouse, the whole process of branching morphogenesis then fails—a primary bud of lung epithelium is formed but fails to grow out into the mesenchyme to create a bronchial tree. Conversely, a microscopic bead soaked in FGF10 and placed near embryonic lung epithelium in culture will induce a bud to form and grow out toward it. Evidently, the epithelium invades the mesenchyme only by invitation, in response to FGF10.

But what makes the growing epithelial tubes branch repeatedly as they invade? This seems to depend on a Sonic hedgehog signal that is sent in the opposite direction, from the epithelial cells at the tips of the buds back to the mesenchyme. In mice lacking Sonic hedgehog, the lung epithelium grows and differentiates, but forms a sac instead of a branching tree of tubules. Meanwhile, FGF10, instead of being restricted to small clusters of mesenchyme cells, with each cluster acting as a beacon to direct the outgrowth of a separate epithelial bud, is expressed in broad bands of cells immediately adjacent to the epithelium. This finding suggests that the Sonic hedgehog signal may serve to shut off FGF10 expression in the mesenchyme cells closest to the growing tip of a bud, splitting the FGF10-secreting cluster into two separate clusters, which in turn cause the bud to branch into two (see [Figure 21-87A](#)).

Many aspects of this system are still not understood, but it is known that *Drosophila* uses closely related mechanisms to govern the branching morphogenesis of its tracheal system—the tubules that form the airways of an insect. Again, the process depends on the *Drosophila* FGF protein, encoded by the *branchless* gene, and the *Drosophila* FGF receptor, encoded by the *breathless* gene, both operating in much the same way as in the mouse. Indeed,

genetic studies of tracheal development in *Drosophila* have also identified other components of the control machinery, and the *Drosophila* genes have led us to their vertebrate homologs. Genetic manipulations in the mouse have given us the means to test whether these genes have similar functions in mammals too; and to a remarkable extent they do. [↑ TOP](#)

Summary

The mouse has a central role as model organism for study of the molecular genetics of mammalian development. Mouse development is essentially similar to that of other vertebrates, but begins with a specialized preamble to form extraembryonic structures such as the amnion and placenta. Powerful techniques have been devised for creation of gene knock-outs and other targeted genetic alterations by exploiting the highly regulative properties of the cells of the inner cell mass of the mouse embryo. These cells can be put into culture and maintained as embryonic stem cells (ES cells). Under the right culture conditions, ES cells can proliferate indefinitely without differentiating, while retaining the ability to give rise to any part of the body when injected back into an early mouse embryo.

Many general developmental processes, including most of those discussed elsewhere in the chapter, have been illuminated by studies in the mouse. As just one example, the mouse has been used to investigate the control of branching morphogenesis. This process gives rise to structures such as lungs and glands, and is governed by exchanges of signals, between mesenchyme cells and an invading epithelium. The functions of these signals can be analyzed by gene knock-out experiments. [↑ TOP](#)

Development of Multicellular Organisms

Neural Development

Nerve cells, or neurons, are among the most ancient of all specialized animal cell types. Their structure is like that of no other class of cells, and the development of the nervous system poses problems that have no real parallel in other tissues. A neuron is extraordinary above all for its enormously extended shape, with a long *axon* and branching *dendrites* connecting it through synapses to other cells (Figure 21-88). The central challenge of neural development is to explain how the axons and dendrites grow out, find their right partners, and synapse with them selectively to create a functional network (Figure 21-89). The problem is formidable: the human brain contains more than 10^{11} neurons, each of which, on average, has to make connections with a thousand others, according to a regular and predictable wiring plan. The precision required is not so great as in a man-made computer, for the brain performs its computations in a different way and is more tolerant of vagaries in individual components; but the brain nevertheless outstrips all other biological structures in its organized complexity.

The components of a typical nervous system—the various classes of neurons, *glial cells*, *sensory cells*, and muscles—originate in a number of widely separate locations in the embryo and are initially unconnected. Thus, in the first phase of neural development (Figure 21-90), the different parts develop according to their own local programs: neurons are born and assigned specific characters according to the place and time of their birth, under the control of inductive signals and gene regulatory mechanisms similar to those we have already discussed for other tissues of the body. The next phase involves a type of morphogenesis unique to the nervous system: axons and dendrites grow out along specific routes, setting up a provisional but orderly network of connections between the separate parts of the system. In the third and final phase, which continues into adult life, the connections are adjusted and refined through interactions among the far-flung components in a way that depends on the electrical signals that pass between them.

Neurons are almost always produced in association with glial cells, which provide a supporting framework and create an enclosed, protected environment in which the neurons can perform their functions. Both cell types, in all animals, develop from the ectoderm, usually as sister cells or cousins derived from a common precursor. Thus, in vertebrates, the neurons and glial cells of the *central nervous system* (including the spinal cord, the brain, and the retina of the eye) derive from the part of the ectoderm that rolls up to form the neural tube, while those of the *peripheral nervous system* derive mainly from the neural crest ([Figure 21-91](#)).

The neural tube, with which we shall be mainly concerned, consists initially of a single-layered epithelium ([Figure 21-92](#)). The epithelial cells are the progenitors of the neurons and glia. As these cell types are generated, the epithelium becomes thickened and transformed into a more complex structure. Progenitor and, later, glial cells maintain the cohesiveness of the epithelium and form a scaffolding that spans its thickness. Along and between these tall cells, like animals amid the trees of the forest, the new-born neurons migrate, find their resting places, mature, and send out their axons and dendrites ([Figure 21-93](#)).

Signal proteins secreted from the ventral and dorsal sides of the neural tube act as opposing morphogens, causing neurons born at different dorsoventral levels to express different gene regulatory proteins ([Figure 21-94](#)). There are differences along the head-to-tail axis as well, reflecting the anteroposterior pattern of expression of Hox genes and the actions of yet other morphogens. Moreover, neurons continue to be generated in each region of the central nervous system over many days, weeks, or even months, and this gives rise to still greater diversity, because the cells adopt different characters according to their "birthday"—the time of the terminal mitosis that marks the beginning of neuronal differentiation ([Figure 21-95](#)). [↑ TOP](#)

The Character Assigned to a Neuron at Its Birth Governs the Connections It Will Form

The differences of gene expression modulate the characters of the neurons and help to cause them to make connections with different partners. In the spinal cord, for example, ventrally located clusters of cells express genes of the *Islet/Lim* homeobox family (coding for gene regulatory proteins) and develop as motor neurons, sending out axons to connect with specific subsets of muscles—different muscles according to the particular *Islet/Lim* family members expressed. If the pattern of gene expression is artificially altered, the neurons project to different target muscles.

The different destinations reflect different pathway choices that the axons make as they grow out from the nerve cell body, as well as their selective recognition of different target cells at the end of the journey. In the dorsal part

[Figure 21-101. A map of the body...](#)[Figure 21-102. Selectivity of retinal axons growing...](#)[Figure 21-103. Sharpening of the retinotectal map...](#)[Figure 21-104. Synapse modification and its dependence...](#)[Figure 21-105. Ocular dominance columns in the...](#)

of the spinal cord lie neurons that receive and relay sensory information from sensory neurons in the periphery of the body. In intermediate positions, there are various other classes of interneurons, connecting specific sets of nerve cells to one another. Some send their axons dorsally, others ventrally; some up toward the head, others down toward the tail, still others across the floor of the neural tube to the other side of the body ([Figure 21-96](#)). In a timelapse film where the developing neurons are stained with a fluorescent dye, one can watch the movements of the growing tips of the axons as they extend: one is reminded of the lights of rush-hour traffic at night, as the cars streak along a network of highways, turning this way or that at busy junctions, each one making its own choice of route.

How are these complex movements guided? Before attempting an answer, we must examine more closely the structure of the growing neuron. [↑ TOP](#)

Each Axon or Dendrite Extends by Means of a Growth Cone at Its Tip

A typical neuron sends out one long axon, projecting toward a distant target to which signals are to be delivered, and several shorter dendrites, on which it mainly receives incoming signals from axon terminals of other neurons. Each process extends by growth at its tip, where an irregular, spiky enlargement is seen. This structure, called the growth cone, appears to be crawling through the surrounding tissue, trailing a slender axon or dendrite behind it (see [Figure 21-96](#)). The growth cone comprises both the engine that produces the movement and the steering apparatus that directs the tip of each process along the proper path (see [Figure 16-99](#)).

Much of what we know about the properties of growth cones has come from studies in tissue or cell culture. One can watch as a neuron begins to put out its processes, all at first alike, until one of the growth cones puts on a sudden turn of speed, identifying its process as the axon, with its own axon-specific set of proteins ([Figure 21-97](#)). The contrast between axon and dendrite established at this stage involves polarized intracellular transport of different materials into the two types of process. As a result, they will grow out for different distances, follow different paths, and play different parts in synapse formation.

The growth cone at the end of a typical growing nerve cell process—either axon or dendrite—moves forward at a speed of about 1 mm per day, continually probing the regions that lie ahead and on either side by putting out filopodia and lamellipodia. When such a protrusion contacts an unfavorable surface, it withdraws; when it contacts a more favorable surface, it persists longer, steering the growth cone as a whole to move in that direction. In this way the growth cone can be guided by subtle variations in the surface properties of the substrata over which it moves. At the same time, it is sensitive to diffusible chemotactic factors in the surrounding medium, which can also encourage or hinder its advance. These behaviors depend on the

cytoskeletal machinery inside the growth cone, as discussed in [Chapter 16](#). A multitude of receptors in the growth cone membrane detect the external signals and, through the agency of intracellular regulators such as the monomeric GTPases Rho and Rac, control the assembly and disassembly of actin filaments and other components of the machinery of cell movement. [↑ TOP](#)

The Growth Cone Pilots the Developing Neurite Along a Precisely Defined Path *in vivo*

In living animals, growth cones generally travel toward their targets along predictable, stereotyped routes, exploiting a multitude of different cues to find their way, but always requiring a substratum of extracellular matrix or cell surface to crawl over. Often, growth cones take routes that have been pioneered by other neurites, which they follow by contact guidance. As a result, nerve fibers in a mature animal are usually found grouped together in tight parallel bundles (called fascicles or fiber tracts). Such crawling of growth cones along axons is thought to be mediated by homophilic cell-cell-adhesion molecules—membrane glycoproteins that help a cell displaying them to stick to any other cell that also displays them. As discussed in [Chapter 19](#), two of the most important classes of such molecules are those that belong to the immunoglobulin superfamily, such as N-CAM, and those of the Ca^{2+} -dependent cadherin family, such as N-cadherin. Members of both families are generally present on the surfaces of growth cones, of axons, and of various other cell types that growth cones crawl over, including glial cells in the central nervous system and muscle cells in the periphery of the body. The human genome contains more than 100 cadherin genes, for example, and most of them are expressed in the brain (see [Figure 19-28](#)). Different sets of cell-cell adhesion molecules, acting in varied combinations, provide a mechanism for selective neuronal guidance and recognition. Growth cones also migrate over components of the extracellular matrix. Some of the matrix molecules, such as *laminin*, favor axon outgrowth, while others, such as chondroitin sulfate proteoglycans, discourage it.

Growth cones are guided by a succession of different cues at different stages of their journey, and the stickiness of the substratum is not the only thing that matters. Another important part is played by chemotactic factors, secreted from cells that act as beacons at strategic points along the path—some attracting, others repelling. The trajectory of *commissural* axons—those that cross from one side of the body to the other—provides a beautiful example of how a combination of guidance signals can specify a complex path. Commissural axons are a general feature of bilaterally symmetrical animals, because the two sides of the body have to be neurally coordinated. Worms, flies and vertebrates use closely related mechanisms to guide their outgrowth.

In the developing spinal cord of a vertebrate, for example, a large number of neurons send their axonal growth cones ventrally toward the floor plate—a specialized band of cells forming the ventral midline of the neural tube (see

Figure 21-96). The growth cones cross the floor plate and then turn abruptly through a right angle to follow a longitudinal path up toward the brain, parallel to the floor plate but never again crossing it (Figure 21-98A). The first stage of the journey depends on a concentration gradient of the protein *netrin*, secreted by the cells of the floor plate: the commissural growth cones sniff their way toward its source. Netrin was purified from chick embryos, by assaying extracts of neural tissue for an activity that would attract commissural growth cones in a culture dish. Its sequence revealed that it was the vertebrate homolog of a protein already known from *C. elegans*, through genetic screens for mutant worms with misguided axons—called *unc* mutants because they move in an *uncoordinated* fashion. One of the *unc* genes, *unc-6*, codes for the homolog of netrin. Another, *unc-40*, codes for its transmembrane receptor; and this too has a vertebrate homolog, called DCC that is expressed in the commissural neurons and mediates their response to the netrin gradient.

The receptors on each growth cone determine the route it will take: non-commissural neurons in the neural tube, lacking DCC, are not attracted to the floorplate; and neurons expressing a different netrin receptor—called Unc-5H in vertebrates (with a counterpart Unc-5 in the worm)—are actively repelled by the floorplate and send their axons instead toward the roof plate. [↑ TOP](#)

Growth Cones Can Change Their Sensibilities as They Travel

If commissural growth cones are attracted to the floor plate, why do they cross it and emerge on the other side, instead of staying in the attractive territory? And having crossed it, why do they never veer back onto it again? The likely answer lies in another set of molecules, several of which are also conserved between vertebrates and invertebrates. Studies of *Drosophila* mutants with misguided commissural axons first identified three of the key proteins: Slit, Roundabout, and Commissureless.

Slit, like netrin, is produced by midline cells of the developing fly, while its receptor, Roundabout, is expressed in the commissural neurons. Slit, acting on Roundabout, has an effect exactly opposite to that of netrin: it repels the growth cones, blocking entry to the midline territory. Commissureless, however, apparently inhibits Roundabout expression initially so as to make the growth cones blind to this "keep-out" signal. Commissural growth cones supplied with Commissureless protein advance to the midline; as they cross it, they seem to lose their blindfold of Commissureless protein and begin to be repelled. Emerging on the far side, they now have functional Roundabout on their surfaces and are thereby prohibited from re-entry.

In vertebrates, a similar mechanism may operate. Commissural growth cones are at first attracted to the midline, and then change their surface receptor proteins as they cross; in this way they may switch their sensibilities, gaining sensitivity to repulsion by Slit—which is expressed in the floor plate—and

losing sensitivity to attraction by netrin. Repulsion from the midline now prevents them from straying back across it. At the same time, the growth cones apparently become sensitive to another set of repulsive signals, in the form of proteins called semaphorins, which prevent them from traveling back up into the dorsal regions of the spinal cord. Trapped between the two sets of repulsive signals, the growth cones have no choice but to travel in a narrow track, running parallel to the floor plate but never re-entering it ([Figure 21-98B](#)). [↑ TOP](#)

Target Tissues Release Neurotrophic Factors That Control Nerve Cell Growth and Survival

Eventually, axonal growth cones reach the target region where they must halt and make synapses. The neurons that sent out the axons can now begin to communicate with their target cells. Although synapses generally transmit signals in one direction, from axon to either dendrite or muscle, the developmental communications are a two-way affair. Signals from the target tissue not only regulate which growth cones shall synapse where (as we discuss below), but also how many of the innervating neurons shall survive.

Most types of neurons in the vertebrate central and peripheral nervous system are produced in excess; up to 50% or more of them then die soon after they reach their target, even though they appear perfectly normal and healthy up to the time of their death. About half of all the motor neurons that send axons to skeletal muscle, for example, die within a few days after making contact with their target muscle cells. A similar proportion of the sensory neurons that innervate the skin die after their growth cones have arrived there.

This large-scale death of neurons is thought to reflect the outcome of a competition. Each type of target cell releases a limited amount of a specific neurotrophic factor that the neurons innervating that target require to survive. The neurons apparently compete for the factor, and those that do not get enough die by programmed cell death. If the amount of target tissue is increased—for example, by grafting an extra limb bud onto the side of the embryo—more limb-innervating neurons survive; conversely, if the limb bud is cut off, the limb-innervating neurons all die. In this way, although individuals may vary in their bodily proportions, they always retain the right number of motor neurons to innervate all their muscles and the right number of sensory neurons to innervate their whole body surface. The seemingly wasteful strategy of overproduction followed by death of surplus cells operates in almost every region of the nervous system. It provides a simple and effective means to adjust each population of innervating neurons according to the amount of tissue requiring innervation.

The first neurotrophic factor to be identified, and still the best characterized, is known simply as nerve growth factor, or NGF—the founding member of the *neurotrophin* family of signal proteins. It promotes the survival of specific

classes of sensory neurons derived from the neural crest and of sympathetic neurons (a subclass of peripheral neurons that control contractions of smooth muscle and secretion from exocrine glands), NGF is produced by the tissues that these neurons innervate. When extra NGF is provided, extra sensory and sympathetic neurons survive, just as if extra target tissue were present. Conversely, in a mouse with a mutation that knocks out the NGF gene or its receptor (a transmembrane tyrosine kinase called TrkA), almost all sympathetic neurons and the NGF-dependent sensory neurons are lost. There are many neurotrophic factors, only a few of which belong to the neurotrophin family, and they act in different combinations to promote survival of different classes of neurons.

NGF and its relatives have an additional role: besides acting on the nerve cell as a whole to control its survival, they regulate the outgrowth of axons and dendrites ([Figure 21-99](#)). These can even act locally on just one part of the tree of nerve cell processes, promoting or pruning the growth of individual branches: a growth cone exposed to NGF shows an immediate increase of motility. Conversely, an axon branch that is deprived of NGF, while the rest of the neuron continues to be bathed in the factor, dies back.

The peripheral action of NGF continues to be important after the phase of neuronal death. In the skin, for example, it controls the branching of sensory nerve fibers, ensuring not only that the whole body surface becomes innervated during development but also that it recovers its innervation after damage. [↑ TOP](#)

Neuronal Specificity Guides the Formation of Orderly Neural Maps

In many cases, axons originating from neurons of a similar type but located in different positions come together for the journey and arrive at the target in a tight bundle. There they disperse again, to terminate at different sites in the target territory.

The projection from the eye to the brain provides an important example. The neurons in the retina that convey visual information back to the brain are called *retinal ganglion cells*. There are more than a million of them, each one reporting on a different part of the visual field. Their axons converge on the optic nerve head at the back of the eye and travel together along the optic stalk into the brain. Their main site of termination, in most vertebrates other than mammals, is the *optic tectum*—a broad expanse of cells in the midbrain. In connecting with the tectal neurons, the retinal axons distribute themselves in a predictable pattern according to the arrangement of their cell bodies in the retina: ganglion cells that are neighbors in the retina connect with target cells that are neighbors in the tectum. The orderly projection creates a **map** of visual space on the tectum ([Figure 21-100](#)).

Orderly maps of this sort are found in many brain regions. In the auditory system, for example, neurons project from the ear to the brain in a tonotopic order, creating a map in which brain cells receiving information about sounds of different pitch are ordered along a line, like the keys of a piano. And in the somatosensory system, neurons conveying information about touch map onto the cerebral cortex so as to mark out a "homunculus"—a small, distorted, two dimensional image of the body surface ([Figure 21-101](#)).

The retinotopic map of visual space in the optic tectum is the best characterized of all these maps. How does it arise? In principle, the growth cones could be physically channeled to different destinations as a consequence of their different starting positions, like drivers on a multilane highway where it is forbidden to change lanes. This possibility was tested in the visual system by a famous experiment in the 1940s. If the optic nerve of a frog is cut, it will regenerate. The retinal axons grow back to the optic tectum, restoring normal vision. If, in addition, the eye is rotated in its socket at the time of cutting of the nerve, so as to put originally ventral retinal cells in the position of dorsal retinal cells, vision is still restored, but with an awkward flaw: the animal behaves as though it sees the world upside down and left-right inverted. This is because the misplaced retinal cells make the connections appropriate to their original, not their actual, positions. It seems that the cells have positional values—position-specific biochemical properties representing records of their original location. As a result, cells on opposite sides of the retina are intrinsically different, just as the motor neurons in the spinal cord that project to different muscles are intrinsically different.

Such nonequivalence among neurons is referred to as *neuronal specificity*. It is this intrinsic characteristic that guides the retinal axons to their appropriate target sites in the tectum. Those target sites themselves are distinguishable by the retinal axons because the tectal cells also carry positional labels. Thus the neuronal map depends on a correspondence between two systems of positional markers, one in the retina and the other in the tectum. [↑ TOP](#)

Axons From Different Regions of the Retina Respond Differently to a Gradient of Repulsive Molecules in the Tectum

Axons from the nasal retina (the side closest to the nose) project to the posterior tectum, and axons from the temporal retina (the side farthest from the nose) project to the anterior tectum, with intermediate regions of retina projecting to intermediate regions of tectum. When nasal and temporal axons are allowed to grow out over a carpet of anterior or posterior tectal membranes in a culture dish, they also show selectivity ([Figure 21-102](#)). Temporal axons strongly prefer the anterior tectal membranes, as *in vivo*, whereas nasal axons either prefer posterior tectal membranes, or show no preference (depending on the species of animal). The key difference between anterior and posterior tectum appears to be a repulsive factor on the posterior tectum, to which

temporal retinal axons are sensitive but nasal retinal axons are not: if a temporal retinal growth cone touches posterior tectal membrane, it collapses its filopodia and withdraws.

Assays based on these phenomena *in vitro* have identified some of the molecules responsible. The repulsive factor on posterior tectal membrane seems to be partly or entirely comprised of *ephrin A* proteins, a subset of the family of GPI-linked proteins that act as ligands for the *Eph family* of tyrosine kinase receptors. In the mouse, two different ephrins are expressed to form an anterior-to-posterior gradient on the tectal cells. Anterior cells have little or no ephrin, cells in the center of the tectum express ephrin A2, and cells at the posterior edge of the tectum express ephrin A2 and ephrin A5. Thus there is a gradient of ephrin expression across the tectum. Meanwhile, the incoming axons express Eph receptors, also in a gradient: temporal axons express high Eph levels, making them sensitive to repulsion by ephrin A, whereas nasal axons express low Eph levels.

This system of signals and receptors is enough to produce an orderly map, if we make one further assumption—an assumption supported by experiments *in vivo*: that the retinal axons somehow interact with one another and compete for tectal territory. Thus, temporal axons are restricted to anterior tectum, and drive nasal axons off it; nasal axons, consequently, are restricted to posterior tectum. Between the extremes, a balance is struck, creating a smooth map of the temporo-nasal axis of the retina onto the anteroposterior axis of the tectum. Ephrin gene knockout studies in the mouse are consistent with this picture, although they also indicate that additional cues help to guide the pattern of retino-tectal projections. Moreover, the map also has to be patterned along the dorsoventral axis; it is thought that this depends on similar mechanisms, perhaps even involving some of the same molecules. [↑ TOP](#)

Diffuse Patterns of Synaptic Connections Are Sharpened by Activity-Dependent Remodeling

In a normal animal the retinotectal map is initially fuzzy and imprecise: the system of matching markers we have just described is enough to define the broad layout of the map, but not sufficient to specify its fine details. Studies in frogs and fish show that each retinal axon at first branches widely in the tectum and makes a profusion of synapses, distributed over a large area of tectum that overlaps with the territories innervated by other axons. These territories are subsequently trimmed back by selective elimination of synapses and retraction of axon branches. This is accompanied by the formation of new sprouts, through which each axon develops a denser distribution of synapses in the territory that it retains.

A central part in this remodeling and refinement of the map is played by two competition rules that jointly help to create spatial order: (1) axons from separate regions of retina, which tend to be excited at different times, compete

to dominate the available tectal territory, but (2) axons from neighboring sites in the retina, which tend to be excited at the same time, innervate neighboring territories in the tectum because they collaborate to retain and strengthen their synapses on shared tectal cells ([Figure 21-103](#)). The mechanism underlying both these rules depends on electrical activity and signaling at the synapses that are formed. If all action potentials are blocked by a toxin that binds to voltage-gated Na^+ channels, synapse remodeling is inhibited and the map remains fuzzy.

The phenomenon of activity-dependent synapse elimination is encountered in almost every part of the developing vertebrate nervous system. Synapses are first formed in abundance and distributed over a broad target field; then the system of connections is pruned back and remodeled by competitive processes that depend on electrical activity and synaptic signaling. The elimination of synapses in this way is distinct from the elimination of surplus neurons by cell death, and it occurs after the period of normal neuronal death is over.

Much of what we know about the cellular mechanisms of synapse formation and elimination comes from experiments on the innervation of skeletal muscle in vertebrate embryos. A two-way exchange of signals between the nerve axon terminals and the muscle cells controls the initial formation of synapses. At sites of contact, acetylcholine receptors are clustered in the muscle cell membrane and the apparatus for secretion of this neurotransmitter becomes organized in the axon terminals (see [Chapter 11](#)). Each muscle cell at first receives synapses from several neurons; but in the end, through a process that typically takes a couple of weeks, it is left innervated by only one. The synapse retraction again depends on synaptic communication: if synaptic transmission is blocked by a toxin that binds to the acetylcholine receptors in the muscle cell membrane, the muscle cell retains its multiple innervation beyond the normal time of elimination.

Experiments on the musculoskeletal system, as well as in the retinotectal system, suggest that it is not only the amount of electrical activity at a synapse that is important for its maintenance, but also its temporal coordination. Whether a synapse is strengthened or weakened seems to depend critically on whether or not activity in the presynaptic cell is synchronized with activity of the other presynaptic cells synapsing on the same target (and thus also synchronized with activity of the target cell itself).

These and many other findings have suggested a simple interpretation of the competition rules for synapse elimination in the retinotectal system ([Figure 21-104](#)). Axons from different parts of the retina fire at different times and so compete. Each time one of them fires, the synapse(s) made by the other on a shared tectal target cell are weakened, until one of the axons is left in sole command of that cell. Axons from neighboring retinal cells, on the other hand, tend to fire in synchrony with one another: they therefore do not compete but instead maintain synapses on shared tectal cells, creating a precisely ordered map in which neighboring cells of the retina project to neighboring sites in the

Experience Molds the Pattern of Synaptic Connections in the Brain

The phenomenon that we have just described is summed up in the catch-phrase that "neurons that fire together, wire together". The same firing rule relating synapse maintenance to neural activity helps to organize our developing brains in the light of experience.

In the brain of a mammal, axons relaying inputs from the two eyes are brought together in a specific cell layer in the visual region of the cerebral cortex. Here, they form two overlapping maps of the external visual field, one as perceived through the right eye, the other as perceived through the left. Although there is some evidence of a tendency for right- and left-eye inputs to be segregated even before synaptic communication begins, a large proportion of the axons carrying information from the two eyes at early stages synapse together on shared cortical target cells. A period of early signaling activity, however, occurring spontaneously and independently in each retina even before vision begins, leads to a clean segregation of inputs, creating stripes of cells in the cortex that are driven by inputs from the right eye alternating with stripes that are driven by inputs from the left eye ([Figure 21-105](#)). The firing rule suggests a simple interpretation: a pair of axons bringing information from neighboring sites in the left eye will frequently fire together, and therefore wire together, as will a pair of axons from neighboring sites in the right eye; but a right-eye axon and a left-eye axon will rarely fire together, and will instead compete. Indeed, if activity from both eyes is silenced using drugs that block action potentials or synaptic transmission, the inputs fail to segregate correctly.

Maintenance of the pattern of connections is extraordinarily sensitive to experience early in life. If, during a certain *critical period* (ending at about the age of five years in humans), one eye is kept covered for a time so as to deprive it of visual stimulation, while the other eye is allowed normal stimulation, the deprived eye loses its synaptic connections to the cortex and becomes almost entirely, and irreversibly, blind. In accordance with what the firing rule would predict, a competition has occurred in which synapses in the visual cortex made by inactive axons are eliminated while synapses made by active axons are consolidated. In this way cortical territory is allocated to axons that carry information and is not wasted on those that are silent.

In establishing the nerve connections that enable us to see, it is not only the quantity of visual stimulation that is important, but also its temporal coordination. For example, the ability to see depth—stereo vision—depends on cells in other layers of the visual cortex that receive inputs relayed from both eyes at once, conveying information about the same part of the visual field as seen from two slightly different angles. These binocularly driven cells allow us to compare the view through the right eye with that through the left so

as to derive information about the relative distances of objects from us. If, however, the two eyes are prevented during the critical period from ever seeing the same scene at the same time—for example, by covering first one eye and then the other on alternate days or simply as a consequence of a childhood squint—almost no binocularly driven cells are retained in the cortex, and the capacity for stereo perception is irretrievably lost. Evidently, in accordance with the firing rule, the inputs from each eye to a binocularly driven neuron are maintained only if the two inputs are frequently triggered to fire in synchrony, as occurs when the two eyes look together at the same scene. [↑ TOP](#)

Adult Memory and Developmental Synapse Remodeling May Depend on Similar Mechanisms

We saw in [Chapter 11](#) that synaptic changes underlying memory in at least some parts of the adult brain, notably the hippocampus, hinge on the behavior of a particular type of receptor for the neurotransmitter glutamate—the NMDA receptor. Ca^{2+} flooding into the postsynaptic cell through the channels opened by this receptor triggers lasting changes in the strengths of the synapses on that cell, affecting the presynaptic as well as the postsynaptic structures. The changes that are induced by the NMDA-dependent mechanism in the adult brain obey rules closely akin to the developmental firing rule: events in the external world that cause two neurons to be active at the same time, or in quick succession, favor the making or strengthening of synapses between them. This condition, called the *Hebb rule*, has been suggested to be the fundamental principle underlying associative learning.

Is it possible, then, that adult learning and the more drastic forms of synaptic plasticity seen during development both reflect the operation of the same basic machinery of synapse adjustment? There are many hints that it may be so. For example, inhibitors that specifically block activation of the NMDA receptor have been found to interfere with the refinement and remodeling of synaptic connections in the developing visual system. But the question is still open. The molecular basis of the processes of synapse remodeling through which experience molds our brains remains one of the central challenges that the nervous system presents to cell biology. [↑ TOP](#)

Summary

The development of the nervous system proceeds in three phases: first, nerve cells are generated through cell division; then, having ceased dividing, they send out axons and dendrites to form profuse synapses with other, remote cells so that communication can begin; last, the system of synaptic connections is refined and remodeled according to the pattern of electrical activity in the neural network.

The neurons, and the glial cells that always accompany them, are generated from ectodermal precursors, and those born at different times and places

express different sets of genes, which help to determine the connections they will form. Axons and dendrites grow out from the neurons by means of growth cones, which follow specific pathways delineated by signals along the way. Structures such as the floor plate of the embryonic spinal cord secrete both chemoattractants and chemorepellents, to which growth cones from different classes of neurons respond differently. On reaching their target area, the axons terminate selectively on a subset of the accessible cells, and in many parts of the nervous system neural maps are set up—orderly projections of one array of neurons onto another. In the retinotectal system, the map is based on the matching of complementary systems of position-specific cell-surface markers—ephrins and Eph receptors—possessed by the two sets of cells.

After the growth cones have reached their targets and initial connections have formed, two major sorts of adjustment occur. First, many of the innervating neurons die as a result of a competition for survival factors such as NGF (nerve growth factor) secreted by the target tissue. This cell death adjusts the quantity of innervation according to the size of the target. Second, individual synapses are pruned away in some places, reinforced in others, so as to create a more precisely ordered pattern of connections. This latter process depends on electrical activity: synapses that are frequently active are reinforced, and different neurons contacting the same target cell tend to maintain their synapses on the shared target only if they are both frequently active at the same time. In this way the structure of the brain can be adjusted to reflect the connections between events in the external world. The underlying molecular mechanism of this synaptic plasticity may be similar to that responsible for the formation of memories in adult life. [↑ TOP](#)

Figure 21-91. Diagram of a 2-day chick embryo, showing the origins of the nervous system. The neural tube (light green) has already closed, except at the tail end, and lies internally, beneath the ectoderm, of which it was originally a part (see Figure 21-76). The neural crest (red) lies dorsally just beneath the ectoderm, in or above the roof of the neural tube. In addition, thickenings, or placodes (dark green), in the ectoderm of the head give rise to some of the sensory transducer cells and neurons of that region, including those of the ear and the nose. The cells of the retina of the eye, by contrast, originate as part of the neural tube.

Figure 21-93. Migration of immature neurons. Before sending out axons and dendrites, newborn neurons often migrate from their birthplace and settle in some other location. The diagrams are based on reconstructions from sections of the cerebral cortex of a monkey (part of the neural tube). The neurons go through their final cell division close to the inner, luminal face of the neural tube and then migrate outward by crawling along *radial glial cells*. Each of these cells extends from the inner to the outer surface of the tube, a distance that may be as much as 2 cm in the cerebral cortex of the developing

Figure 21-94. A schematic cross section of the spinal cord of a chick embryo, showing how cells at different levels along the dorsoventral axis express different gene regulatory proteins. (A) Signals that direct the dorsoventral pattern: Sonic hedgehog protein from the notochord and the floor plate (the ventral midline of the neural tube) and BMP proteins from the roof plate (the dorsal midline) act as morphogens to control gene expression. (B) The resulting patterns of gene expression in the ventral part of the developing spinal cord. Different groups of proliferating neural progenitor cells (in the *ventricular zone*, close to the lumen of the neural tube) and of differentiating neurons (in the *mantle zone*, further out) express different combinations of gene regulatory proteins. Those indicated in this diagram are almost all members of the homeodomain superfamily; various other genes of the same superfamily (including Islet/Lim proteins) are expressed in the differentiating neurons. Neurons expressing different gene regulatory proteins will form connections with different partners and may make different combinations of neurotransmitters and receptors.

Figure 21-95. Programmed production of different types of neurons at different times from dividing progenitors in the cerebral cortex of the brain of a mammal. Close to one face of the cortical neuroepithelium, progenitor cells divide repeatedly, in stem-cell fashion, to produce neurons. The neurons migrate out toward the opposite face of the epithelium by crawling along the surfaces of radial glial cells, as shown in [Figure 21-93](#). The first-born neurons settle closest to their birthplace, while neurons born later crawl past them to settle farther out. Successive generations of neurons thus occupy different layers in the cortex and have different intrinsic characters according to their birth dates.

Figure 21-96. Growing axons in the developing spinal cord of a 3-day chick embryo. The drawing shows a cross section stained by the Golgi technique. Most of the neurons, apparently, have as yet only one elongated process—the future axon. An irregularly shaped expansion—a growth cone—is seen at the growing tip of each axon. The growth cones of the motor neurons emerge from the spinal cord (to make their way toward muscles), those of the sensory neurons grow into it from outside (where their cell bodies lie), and those of the interneurons remain inside the spinal cord. Many of the interneurons send their axons down toward the floor plate to cross to the other side of the spinal cord; these axons are called *commissural*. At this early stage, many of the embryonic spinal-cord cells (in the regions shaded gray) are still proliferating and have not yet begun to differentiate as neurons or glial cells. (From S. Ramón y Cajal, *Histologie du Système Nerveux de l'Homme et des Vertébrés*, 1909–1911. Paris: Maloine; reprinted, Madrid: C.S.I.C., 1972.)

Figure 21-98. The guidance of commissural axons. (A) The pathway taken by commissural axons in the embryonic spinal cord of a vertebrate. (B) The signals that guide them. The growth cones are first attracted to the floorplate by netrin, which is secreted by the floor-plate cells and acts on the receptor DCC in the axonal membrane. As they cross the floor plate, the growth cones upregulate their expression of Roundabout, the receptor for a repellent protein, Slit, that is also secreted by the floor plate. Slit, binding to Roundabout, not only acts as a repellent to keep the cells from re-entering the floor plate, but also blocks responsiveness to the attractant netrin. At the same time, the growth cones switch on expression of receptors for another repellent protein, semaphorin, that is secreted by the cells in the side walls of the neural tube. Trapped between two repellent territories, the growth cones, having crossed the midline, travel in a tight fascicle up toward the brain.

control

Figure 21-99. NGF effects on neurite outgrowth. Dark-field photomicrographs of a sympathetic ganglion cultured for 48 hours with (*above*) or without (*below*) NGF. Neurites grow out from the sympathetic neurons only if NGF is present in the medium. Each culture also contains Schwann (glial) cells that have migrated out of the ganglion; these are not affected by NGF. Neuronal survival and maintenance of growth cones for neurite extension represent two distinct effects of NGF. The effect on growth cones is local, direct, rapid, and independent of communication with the cell body; when NGF is removed, the deprived growth cones halt their movements within a minute or two. The effect of NGF on cell survival is less immediate

Figure 21-101. A map of the body surface in the human brain. The surface of the body is mapped onto the somatosensory region of the cerebral cortex by an orderly system of nerve cell connections, such that sensory information from neighboring body sites is delivered to neighboring sites in the brain. This means that the map in the brain is largely faithful to the topology of the body surface, even though different body regions are represented at different magnifications according to their density of innervation. The homunculus (the "little man" in the brain) has big lips, for example, because the lips are a particularly large and important source of sensory information. The map was determined by stimulating different points in the cortex of conscious patients during brain surgery and recording what they said they felt. (After W. Penfield and T. Rasmussen, *The Cerebral Cortex of Man*. New York: Macmillan, 1950.)

Figure 21-102. Selectivity of retinal axons growing over tectal membranes. (A) A photograph of the experimental observation. (B) A diagram of what is happening. The culture substratum has been coated with alternating stripes of membrane prepared either from posterior tectum (P) or from anterior tectum (A). In the photograph, the anterior tectal stripes are made visible by staining them with a fluorescent marker in the vertical strips at the sides of the picture. Axons of neurons from the temporal half of the retina (growing in from the *left*) follow the stripes of anterior tectal membrane but avoid the posterior tectal membrane, while axons of neurons from the nasal half of the retina (growing in from the *right*) do the converse. Thus anterior tectum differs from posterior tectum and nasal retina from temporal retina, and the differences guide selective axon outgrowth. These experiments were performed with cells from the chick embryo. (From Y. von Boxborg, S. Deiss, and U. Schwarz, *Neuron* 10:345–357, 1993. © Elsevier.)

Figure 21-104. Synapse modification and its dependence on electrical activity.

Experiments in several systems indicate that synapses are strengthened or weakened by electrical activity according to the rule shown in the diagram. The underlying principle appears to be that each excitation of a target cell tends to weaken any synapse where the presynaptic axon terminal has just been quiet but to strengthen any synapse where the presynaptic axon terminal has just been active. As a result, "neurons that fire together, wire together." A synapse that is repeatedly weakened and rarely strengthened is eventually eliminated altogether.

Development of Multicellular Organisms

Plant Development

Plants and animals are separated by about 1.5 billion years of evolutionary history. They have evolved their multicellular organization independently but using the same initial tool kit—the set of genes inherited from their common unicellular eucaryotic ancestor. Most of the contrasts in their developmental strategies spring from two basic peculiarities of plants. First, they get their energy from sunlight, not by ingesting other organisms. This dictates a body plan different from that of animals. Second, their cells are encased in semirigid cell walls and cemented together, preventing them from moving as animal cells do. This dictates a different set of mechanisms for shaping the body and different developmental processes to cope with a changeable environment.

Animal development is largely buffered against environmental changes, and the embryo generates the same genetically determined body structure unaffected by external conditions. The development of most plants, by contrast, is dramatically influenced by the environment. Because they cannot match themselves to their environment by moving from place to place, plants adapt instead by altering the course of their development. Their strategy is opportunistic. A given type of organ—a leaf, a flower, or a root, say—can be produced from the fertilized egg by many different paths according to environmental cues. A begonia leaf pegged to the ground may sprout a root; the root may throw up a shoot; the shoot, given sunlight, may grow leaves and flowers.

The mature plant is typically made of many copies of a small set of standardized modules, as described in [Figure 21-106](#). The positions and times at which those modules are generated are strongly influenced by the environment, causing the overall structure of the plant to vary. The choices between alternative modules and their organization into a whole plant depend on external cues and long-range hormonal signals that play a much smaller part in the control of animal development.

But although the global structure of a plant—its pattern of roots or branches, its numbers of leaves or flowers—can be highly variable, its detailed organization on a small scale is not. A leaf, a flower, or indeed an early plant

embryo, is as precisely specified as any organ of an animal, possessing a *determinate* structure, in contrast with the *indeterminate* pattern of branching and sprouting of the plant as a whole. The internal organization of a plant module raises essentially the same problems in the genetic control of pattern formation as does animal development, and they are solved in analogous ways. In this section we focus on the cellular mechanisms of development in flowering plants. We examine both the contrasts and the similarities with animals.

Arabidopsis Serves as a Model Organism for Plant Molecular Genetics

Flowering plants, despite their amazing variety, are of relatively recent origin. The earliest known fossil examples are 125 million years old, as against 350 million years or more for vertebrate animals. Underlying the diversity of form, therefore, there is a high degree of similarity in molecular mechanisms. As we shall see, a small genetic change can transform a plant's large-scale structure; and just as plant physiology allows survival in many different environments, so also it allows survival of many differently structured forms. A mutation that gives an animal two heads is generally lethal; one that doubles the number of flowers or branches on a plant is generally not.

To identify the genes that govern plant development and to discover how they function, plant biologists have selected a small weed, the common wall cress *Arabidopsis thaliana* (Figure 21-107), as their primary model organism. Like *Drosophila* or *Caenorhabditis elegans*, it is small, quick to reproduce, and convenient for genetics. It can be grown indoors in Petri dishes or tiny plant pots in large numbers and produces hundreds of seeds per plant after 8 to 10 weeks. It has, in common with *C. elegans*, a significant advantage over *Drosophila* or vertebrate animals for genetics: like many flowering plants, it can reproduce as a hermaphrodite because a single flower produces both eggs and the male gametes that can fertilize them. Therefore, when a flower that is heterozygous for a recessive lethal mutation is self-fertilized, one-fourth of its seeds will display the homozygous embryonic phenotype. This makes it easy to perform genetic screens (Figure 21-108) and so to obtain a catalog of the genes required for specific developmental processes. [↑ TOP](#)

The *Arabidopsis* Genome Is Rich in Developmental Control Genes

Arabidopsis has one of the smallest plant genomes—125 million nucleotide pairs, on a par with *C. elegans* and *Drosophila*—and the complete DNA sequence is now known. It contains approximately 26,000 genes. This total includes many recently generated duplicates, however, so that the number of functionally distinct types of protein represented may be considerably less. Cell culture and genetic transformation methods have been established, as well as vast libraries of seeds carrying mutations produced by random insertions of

mobile genetic elements, so that plants with mutations in any chosen gene can be obtained to order. Powerful tools are thus available to analyze gene functions. Although only a small fraction of the total gene set has been characterized experimentally as yet, functions can be tentatively assigned to many genes—about 18,000—on the basis of their sequence similarities to well-characterized genes in *Arabidopsis* and other organisms.

Even more than the genomes of multicellular animals, the *Arabidopsis* genome is rich in genes that code for gene regulatory proteins (Table 21-2). Some major families of animal gene regulatory proteins (such as the Myb family of DNA-binding proteins) are greatly expanded, while others (such as nuclear hormone receptors) seem to be entirely absent, and there are large families of gene regulatory proteins in the plant that have no animal homologs.

Where homologous gene regulatory proteins (such as homeodomain proteins) can be recognized in both plants and animals, they have little in common with regard to the genes they regulate or the types of developmental decisions that they control, and there is very little conservation of protein sequence outside the DNA-binding domains.

Arabidopsis is like multicellular animals in possessing many genes for cell communication and signal transduction (1,900 genes out of 18,000 classified), but the specific details of these gene sets are very different, as discussed in Chapter 15. The Wnt, Hedgehog, Notch, and TGF β signaling mechanisms are all absent in *Arabidopsis*. In compensation, other signaling pathways peculiar to plants are highly developed. Cell-surface receptors of the tyrosine kinase class seem to be entirely absent, although many of the signaling components downstream of these receptors in animals are present. Conversely, receptors of the serine/threonine kinase class are very plentiful, but they do not act through the same system of intracellular messengers as the receptor serine/threonine kinases in animals. Substantial sets of genes are devoted to developmental processes of special importance in plants: more than 700 for synthesis and remodelling of the plant cell wall, for example, and more than 100 for detecting and responding to light.

We must now examine how the genes of the plant are used to control plant development. [↑ TOP](#)

Embryonic Development Starts by Establishing a Root-Shoot Axis and Then Halts Inside the Seed

The basic strategy of sexual reproduction in flowering plants is briefly summarized in Panel 21-1. The fertilized egg, or zygote, of a higher plant begins by dividing asymmetrically to establish the polarity of the future embryo. One product of this division is a small cell with dense cytoplasm, which will become the embryo proper. The other is a large vacuolated cell that divides further and forms a structure called the *suspensor*, which in some ways

is comparable to the umbilical cord in mammals. The suspensor attaches the embryo to the adjacent nutritive tissue and provides a pathway for the transport of nutrients.

During the next step in development the diploid embryo cell proliferates to form a ball of cells that quickly acquires a polarized structure. This comprises two key groups of proliferating cells—one at the suspensor end of the embryo that will collaborate with the uppermost suspensor cell to generate a root, and one at the opposite end that will generate a shoot ([Figure 21-109](#)). The main root-shoot axis established in this way is analogous to the head-to-tail axis of an animal. At the same time it begins to be possible to distinguish the future *epidermal cells*, forming the outermost layer of the embryo, the future *ground tissue cells*, occupying most of the interior, and the future *vascular tissue cells*, forming the central core ([Panel 21-2](#)). These three sets of cells can be compared to the three germ layers of an animal embryo. Slightly later in development, the rudiment of the shoot begins to produce the embryonic seed leaves, or *cotyledons*—one in the case of monocots and two in the case of dicots. Soon after this stage, development usually halts and the embryo becomes packaged in a **seed** (a case formed by tissues of the mother plant), specialized for dispersal and for survival in harsh conditions. The embryo in a seed is stabilized by dehydration, and it can remain dormant for a very long time—even hundreds of years. When rehydrated, the seeds germinate and embryonic development resumes.

Genetic screens can be used in *Arabidopsis*, just as in *Drosophila* or *C. elegans*, to identify the genes that govern the organization of the embryo and to group these into categories according to their homozygous mutant phenotypes. Some are required for formation of the seedling root, some for the seedling stem, and some for the seedling apex with its cotyledons. Another class is required for formation of the three major tissue types—epidermis, ground tissue, and vascular tissue—and yet another class for the organized changes of cell shape that give the embryo and seedling their elongated form ([Figure 21-110](#)). [↑ TOP](#)

The Parts of a Plant Are Generated Sequentially by Meristems

Roughly speaking, the embryo of an insect or a vertebrate animal is a rudimentary miniature scale model of the later organism, and the details of body structure are filled in progressively as it enlarges. The plant embryo grows into an adult in a quite different way: the parts of the adult plant are created sequentially by groups of cells that proliferate to lay down additional structures at the plant's periphery. These all-important groups of cells are called **apical meristems** (see [Figure 21-106](#)). Each meristem consists of a self-renewing population of stem cells. As these divide, they leave behind a trail of progeny that become displaced from the meristem region, enlarge, and finally differentiate. Although the shoot and root apical meristems generate all the

basic varieties of cells that are needed to build leaves, roots, and stems, many cells outside the apical meristems also keep a capacity for further proliferation and retain meristem potential. In this way trees and other perennial plants, for example, are able to increase the girth of their stems and roots as the years go by and can sprout new shoots from dormant regions if the plant is damaged.

The rudiments of the apical meristems of root and shoot are already determined in the embryo. As soon as the seed coat ruptures during germination, a dramatic enlargement of nonmeristematic cells occurs, driving the emergence first of a root, to establish an immediate foothold in the soil, and then of a shoot ([Figure 21-111](#)). This is accompanied by rapid and continual cell divisions in the apical meristems: in the apical meristem of a maize root, for example, cells divide every 12 hours, producing 5×10^5 cells per day. The rapidly growing root and shoot probe the environment—the root increasing the plant's capacity for taking up water and minerals from the soil, the shoot increasing its capacity for photosynthesis (see [Panel 21-1](#)). [↑ TOP](#)

Development of the Seedling Depends on Environmental Signals

From germination onward, the course of plant development is powerfully influenced by signals from the environment. The shoot has to push its way rapidly up through the soil, and must open its cotyledons and begin photosynthesis only after it has reached the light. The timing of this transition from rapid subterranean sprouting to illuminated growth cannot be genetically programmed, because the depth at which the seed is buried is unpredictable. The developmental switch is controlled instead by light, which, among other effects, acts on the seedling by inhibiting production of a class of plant hormones called *brassinosteroids*, discussed in [Chapter 15](#). Mutations in genes required for production or reception of the brassinosteroid signal cause the stem of the seedling to go green, slow its elongation, and open its cotyledons prematurely, while it is still in the dark. [↑ TOP](#)

The Shaping of Each New Structure Depends on Oriented Cell Division and Expansion

Plant cells, imprisoned within their cell walls, cannot crawl about and cannot be shuffled as the plant grows; but they can divide, and they can swell, stretch, and bend. The morphogenesis of a developing plant therefore depends on orderly cell divisions followed by strictly oriented cell expansions. Most cells produced in the root-tip meristem, for example, go through three distinct phases of development—division, growth (elongation), and differentiation. These three steps, which overlap in both space and time, give rise to the characteristic architecture of a root tip. Although the process of cell differentiation often begins while a cell is still enlarging, it is comparatively easy to distinguish in a root tip a zone of cell division, a zone of oriented cell

elongation (which accounts for the growth in length of the root), and a zone of cell differentiation ([Figure 21-112](#)).

In the phase of controlled expansion that generally follows cell division, the daughter cells may often increase in volume by a factor of 50 or more. This expansion is driven by an osmotically based turgor pressure that presses outward on the plant cell wall, and its direction is determined by the orientation of the cellulose fibrils in the cell wall, which constrain expansion along one axis (see [Figure 19-73](#)). The orientation of the cellulose in turn is apparently controlled by the orientation of arrays of microtubules just inside the plasma membrane, which are thought to guide cellulose deposition (discussed in [Chapter 19](#)). These orientations can be rapidly changed by plant growth regulators, such as ethylene and gibberellic acid ([Figure 21-113](#)), but the molecular mechanisms underlying these dramatic cytoskeletal rearrangements are still unknown. [↑ TOP](#)

Each Plant Module Grows From a Microscopic Set of Primordia in a Meristem

The apical meristems are self-perpetuating: in a perennial plant, they carry on with their functions indefinitely, as long as the plant survives, and they are responsible for its continuous growth and development. But apical meristems also give rise to a second type of outgrowth, whose development is strictly limited and culminates in the formation of a structure such as a leaf or a flower, with a determinate size and shape and a short lifespan. Thus, as a vegetative (non-flowering) shoot elongates, its apical meristem lays down behind itself an orderly sequence of *nodes*, where leaves have grown out, and *internodes* (segments of stem). In this way the continuous activity of the meristem produces an ever increasing number of similar modules, each consisting of a stem, a leaf, and a bud (see [Figure 21-106](#)). The modules are connected to one another by supportive and transport tissue, and successive modules are precisely located relative to each other, giving rise to a repetitively patterned structure. This iterative mode of development is characteristic of plants and is seen in many other structures besides the stem-leaf system ([Figure 21-114](#)).

Although the final module is large, its organization, like that of an animal embryo, is mapped out at first on a microscopic scale. At the apex of the shoot, within a space of a millimeter or less, one finds a small, low central dome surrounded by a set of distinctive swellings in various stages of enlargement ([Figure 21-115](#)). The central dome is the apical meristem itself; each of the surrounding swellings is the primordium of a leaf. This small region, therefore, contains the already distinct rudiments of several entire modules. Through a well-defined program of cell proliferation and cell enlargement, each leaf primordium and its adjacent cells will grow to form a leaf, a node, and an internode. Meanwhile, the apical meristem itself will give rise to new leaf primordia, so as to generate more and more modules in a potentially unending

succession. The serial organization of the modules of the plant is thus controlled by events at the shoot apex. It is the system of local signals within this tiny region that determines the pattern of primordia—the position of one leaf rudiment relative to the next, the spacing between them, and their location relative to the apical meristem itself.

Variations on this basic repetitive theme can give rise to more complex architectures, including structures such as tendrils, thorns, branches, and flowers. Thus, by switching on different sets of genes at the shoot apex, the plant can produce different types of primordia, in different spatial patterns. [↑ TOP](#)

Cell Signaling Maintains the Meristem

Central to all these phenomena is the question of how the apical meristem maintains itself. The meristem cells must continue to proliferate for weeks, years, or even centuries as a plant grows, replacing themselves while continually generating progeny cells that differentiate. Through all this, the size of the cluster of cells that constitute the meristem remains practically constant (about 100 cells in *Arabidopsis*, for example). New meristems may arise as the plant branches, but they too preserve the same size.

Genetic screens have identified genes required for meristem maintenance. For example, mutations that disrupt the *WUSCHEL* gene, which codes for a homeodomain protein, convert the apical meristem into non-meristematic tissue, so that the seedling fails to sprout. Conversely, mutations in the *CLAVATA* group of genes, coding for components of a cell-cell signaling pathway (see [Figure 15-77](#)), make the meristem abnormally big. These genes are expressed in different layers of cells in the meristem region ([Figure 21-116A](#)). The two most superficial cell layers, called the L1 and L2 layers, together with the uppermost part of the L3 layer, contain the cells of the meristem proper, capable of dividing indefinitely to give rise to future parts of the plant. The meristematic cells of the L1 and L2 layers express Clavata3, a small secreted signal protein. Just beneath, in the L3 layer, lies a cluster of cells expressing Clavata1 (the receptor for Clavata3). In the center of this Clavata1 patch are cells that express the Wuschel gene regulatory protein.

The pattern of cell divisions implies that the cells expressing Wuschel are not themselves part of the meristem proper; new Wuschel-expressing cells are apparently continually recruited from the meristematic part of the L3 population, just above the Wuschel domain. Nevertheless, the Wuschel-expressing cells are at the heart of the mechanism that maintains the meristem. A signal that they produce maintains meristematic behavior in the cells above, stimulates expression of the *CLAVATA* genes, and, presumably, causes new cells recruited into the Wuschel domain to switch on Wuschel. Negative feedback from the upper meristematic cells, delivered by the Clavata signaling pathway, acts back on the regions below to limit the size of the Wuschel

domain, thereby preventing the meristem from becoming too big ([Figure 21-116B](#)).

This account of the plant meristem is still uncertain in many details and other genes besides those we have mentioned are also involved. Nevertheless, mathematical modeling shows that systems of a similar sort, based on a feedback loop involving a short-range activating signal and a long-range inhibitory signal, can stably maintain a signaling center of a well-defined size even when there is continual proliferation and turnover of the cells that form that center. Analogous systems of signals are thought to operate in animal development to maintain localized signaling centers—such as the Organizer of the amphibian gastrula, or the zone of polarizing activity in a limb bud.

It is still not known how the Wuschel-expressing cells signal to their neighbors. One possibility is that the Wuschel protein itself diffuses directly from cell to cell through plasmodesmata—a signaling pathway peculiar to plants. Some other gene regulatory proteins have in fact been shown to travel in this way in meristems, spreading from cells that contain the corresponding mRNA into neighboring cells that do not. [↑ TOP](#)

Regulatory Mutations Can Transform Plant Topology by Altering Cell Behavior in the Meristem

If a stem is to branch, new shoot apical meristems must be created, and this too depends on events in the neighborhood of the shoot apex. At each developing node, in the acute angle (the axil) between the leaf primordium and the stem, a bud is formed ([Figure 21-117](#)). This contains a nest of cells, derived from the apical meristem, that keep a meristematic character. They have the capacity to become the apical meristem of a new branch or the primordium of a structure such as a flower; but they also have the alternative option of remaining quiescent as *axillary buds*. The plant's pattern of branching is regulated through this choice of fate, and mutations that affect it can transform the structure of the plant. Maize provides a beautiful example.

Maize represents one of mankind's most remarkable feats of genetic engineering. Native Americans created it by selective breeding, over a period of several centuries or perhaps millennia between 5,000 and 10,000 years ago. They started from a wild grass known as teosinte, with highly branched leafy stems and tiny ears bearing inedible hard kernels. Detailed genetic analysis has identified a handful of genetic loci—about five—as the sites of the mutations that account for most of the difference between this unpromising ancestor and modern corn. One of these loci, with a particularly dramatic effect, corresponds to a gene called *teosinte branched-1* (*tb1*). In maize with loss-of-function mutations in *tb1*, the usual simple unbranched stem, with a few large leaves at intervals along it, is transformed into a dense, branching, leafy mass reminiscent of teosinte ([Figure 21-118A](#)). The pattern of branching in the mutant implies that axillary buds, originating in normal positions, have

escaped from an inhibition that prevents them, in normal maize, from growing into branches.

In normal maize, the single stem is crowned with a tassel—a male flower—while a few of the axillary buds along the stem develop into female flowers and, upon fertilization, form the ears of corn that we eat. In the mutant maize with a defective *tb1* gene, these fruitful axillary buds are transformed into branches bearing tassels. The wild teosinte plant is like the *tb1*-defective maize in its leafy, highly branched appearance, but unlike this mutant it makes ears on many of its side branches, as though *tb1* were active. DNA analysis reveals the explanation. Both teosinte and normal maize possess a functional *tb1* gene, with an almost identical coding sequence, but in maize the regulatory region has undergone a mutation that boosts the level of gene expression. Thus in normal maize the gene is expressed at a high level in every axillary bud, inhibiting branch formation, while in teosinte the expression in many axillary buds is low, so that branches are permitted to form ([Figure 21-118B](#)).

This example shows how simple mutations, by switching the behavior of meristem cells, can transform plant structure—a principle of enormous importance in the breeding of plants for food. More generally, the case of *tb1* illustrates how new body plans, whether of plant or animal, can evolve through changes in regulatory DNA without change in the characters of the proteins made. [↑ TOP](#)

Long-Range Hormonal Signals Coordinate Developmental Events in Separate Parts of the Plant

The fate of an axillary bud is dictated not only by its genes, but also by environmental conditions. Separate parts of a plant experience different environments and react to them individually by changes in their mode of development. The plant, however, must continue to function as a whole. This demands that developmental choices and events in one part of the plant affect developmental choices elsewhere. There must be long-range signals to bring about such coordination.

As gardeners know, for example, by pinching off the tip of a branch one can stimulate side growth: removal of the apical meristem relieves the quiescent axillary meristems of an inhibition and allows them to form new twigs. In this case the long-range signal from the apical meristem, or at least a key component has been identified. It is an auxin, a member of one of six known classes of plant growth regulators (sometimes called *plant hormones*), all of which have powerful influences on plant development. The five other known classes are the *gibberellins*, the *cytokinins*, *abscisic acid*, the gas *ethylene*, and the *brassinosteroids*. As shown in [Figure 21-119](#), all are small molecules that readily penetrate cell walls. They are all synthesized by most plant cells and can either act locally or be transported to influence target cells at a distance. Auxin, for example, is transported from cell to cell at a rate of about 1 cm per

hour from the tip of a shoot toward its base. Each growth regulator has multiple effects, and these are modulated by the other growth regulators, as well as by environmental cues and nutritional status. Thus auxin alone can promote root formation, but in conjunction with gibberellin it can promote stem elongation, with cytokinin, auxin it can suppress lateral shoot outgrowth, and with ethylene it can stimulate lateral root growth. The receptors that recognize some of these growth regulators are discussed in [Chapter 15](#). [↑ TOP](#)

Homeotic Selector Genes Specify the Parts of a Flower

Meristems face other developmental choices besides that between quiescence and growth, as we have already seen in our discussion of maize, and these also are frequently regulated by the environment. The most important is the decision to form a flower ([Figure 21-120](#)).

The switch from meristematic growth to flower formation is typically triggered by light. By poorly understood mechanisms based on light absorption by phytochrome and cryptochrome proteins (discussed in [Chapter 15](#)), the plant can sense very precisely a change in day length. It responds by turning on expression of a set of *floral meristem-identity* genes in the apical meristem. By switching on these genes, the apical meristem abandons its chances of continuing vegetative growth and gambles its future on the production of gametes. Its cells embark on a strictly finite program of growth and differentiation: by a modification of the ordinary mechanisms for generating leaves, a series of whorls of specialized appendages are formed in a precise order—typically sepals first, then petals, then stamens carrying anthers containing pollen, and lastly carpels containing eggs (see [Panel 21-1](#)). By the end of this process the meristem has disappeared, but among its progeny it has created germ cells.

The series of modified leaves forming a flower can be compared to the series of body segments forming a fly. In plants, as in flies, one can find homeotic mutations that convert one part of the pattern to the character of another. The mutant phenotypes can be grouped into at least four classes, in which different but overlapping sets of organs are altered ([Figure 21-121](#)). The first or 'A' class, exemplified by the *apetala2* mutant of *Arabidopsis*, has its two outermost whorls transformed: the sepals are converted into carpels and the petals into stamens. The second or 'B' class, exemplified by *apetala3*, has its two middle whorls transformed: the petals are converted into sepals and the stamens into carpels. The third or 'C' class, exemplified by *agamous*, has its two innermost whorls transformed, with a more drastic consequence: the stamens are converted into petals, the carpels are missing, and in their place the central cells of the flower behave as a floral meristem, which begins the developmental performance all over again, generating another abnormal set of sepals and petals nested inside the first and, potentially, another nested inside that, and so on, indefinitely. A fourth class, the *sepallata* mutants, has its three inner whorls all transformed into sepals.

These phenotypes identify four classes of homeotic selector genes, which, like the homeotic selector genes of *Drosophila*, all code for gene regulatory proteins. These are expressed in different domains and define the differences of cell state that give the different parts of a normal flower their different characters, as shown in [Figure 21-122](#). The gene products collaborate to form protein complexes that drive expression of the appropriate downstream genes. In a triple mutant where the A, B and C genetic functions are all absent, one obtains in place of a flower an indefinite succession of tightly nested leaves (see [Figure 21-121D](#)). Conversely, in a transgenic plant where genes of the A, B and *sepallata* classes are all expressed together outside their normal domains, leaves are transformed into petals. Leaves therefore represent a "ground state" in which none of these homeotic selector genes are expressed, while the other types of organ result from expressing the genes in different combinations.

Similar studies have been carried out in other plant species, and a similar set of phenotypes and genes have been identified: plants, no less than animals, have conserved their homeotic selector gene systems. Gene duplication has played a large part in the evolution of these genes: several of them, required in different organs of the flower, have clearly homologous sequences. These are not of the homeobox class but are members of another family of gene regulatory proteins (the so-called MADS family), also found in yeast and in vertebrates.

Clearly, plants and animals, have independently found very similar solutions to many of the fundamental problems of multicellular development. [↑ TOP](#)

Summary

The development of a flowering plant, like that of an animal, begins with division of a fertilized egg to form an embryo with a polarized organization: the apical part of the embryo will form the shoot, the basal part, the root, and the middle part, the stem. At first, cell division occurs throughout the body of the embryo. As the embryo grows, however, addition of new cells becomes restricted to small regions known as meristems. Apical meristems, at shoot tips and root tips, will persist throughout the life of the plant, enabling it to grow by sequentially adding new body parts at its periphery. Typically, the shoot generates a repetitive series of modules, each consisting of a segment of stem, a leaf, and an axillary bud. An axillary bud is a potential new meristem, capable of giving rise to a side branch; the environment—and long-range hormonal signals within the plant can control the development of the plant by regulating bud activation. Mutations that alter the rules for activating axillary buds can have a drastic effect on the shape and structure of the plant; a single such mutation—one of about five key genetic alterations—accounts for a large part of the dramatic difference between modern maize and its wild ancestor, teosinte.

The small weed *Arabidopsis thaliana* is widely used as a model organism for

genetic studies and is the first plant to have had its genome completely sequenced. As in animals, genes governing plant development can be identified through genetic screens and their functions tested by genetic manipulations. Such studies have begun to reveal the molecular mechanisms by which the internal organization of each plant module is sketched out on a microscopic scale through cell-cell interactions in the neighborhood of the apical meristem. The meristem itself appears to be maintained by a local feedback loop, in which cells expressing the gene regulatory protein Wuschel provide a positive stimulus, and a negative feedback dependent on the Clavata cell-cell signaling pathway keeps the meristem from becoming too big.

Environmental cues—especially light that is appropriately timed—can cause the expression of genes that switch the apical meristem from a leaf-forming to a flower-forming mode. The parts of a flower—its sepals, petals, stamens and carpels—are formed by a modification of the mechanism for development of leaves, and the differences between these parts are controlled by homeotic selector genes that are closely analogous (although not homologous) to those of animals. Each module (shown in different shades of *green*) consists of a stem, a leaf, and a bud containing a potential growth center, or *meristem*. The bud forms at the branch point, or *node*, where the leaf diverges from the stem. Modules arise sequentially from the continuous activity of the apical meristem.

Figure 21-113. The different effects of the plant growth regulators ethylene and gibberellic acid. These regulators exert rapid and opposing effects on the orientation of the cortical microtubule array in cells of young pea shoots. A typical cell in an ethylene-treated plant (B) shows a net longitudinal orientation of microtubules, while a typical cell in a gibberellic-acid-treated plant (C) shows a net transverse orientation. New cellulose microfibrils are deposited parallel to the microtubules. Since this influences the direction of cell expansion, gibberellic acid and ethylene encourage growth in opposing directions: ethylene-treated seedlings will develop short, fat shoots (A), while gibberellicacid-treated seedlings will develop long, thin shoots (D).

Figure 21-115. A shoot apex from a young tobacco plant. (A) A scanning electron micrograph shows the shoot apex with two sequentially emerging leaf primordia, seen here as lateral swellings on either side of the domed apical meristem. (B) A thin section of a similar apex shows that the youngest leaf primordium arises from a small group of cells (about 100) in the outer four or five layers of cells. (C) A very schematic drawing showing that the sequential appearance of leaf primordia takes place over a small distance and very early in shoot development. Growth of the apex will eventually form internodes that will separate the leaves in order along the stem (see [Figure 21-106](#)). (A and B, from R.S. Poethig and I.M. Sussex, *Planta* 165:158–169, 1985. © Springer-Verlag.)

Figure 21-116. The feedback loops that are thought to maintain the shoot apical meristem. (A) The arrangement of cell layers constituting a shoot apical meristem. (B) The pattern of cell-cell communication that maintains the meristem. Artificial overexpression of Wuschel in the L3 region causes an increase in the number of cells in the L1 and L2 layers that behave as meristem cells and express Clavata3; artificial overexpression of Clavata3 in the L1 and L2 layers causes a reduction of Wuschel expression in the L3 region below and a decrease in the number of meristem cells. Clavata3 codes for a small signal protein, while Clavata1 codes for its receptor, a transmembrane protein kinase. Wuschel, which is expressed in the central part of the region that expresses the receptor Clavata1, codes for a gene regulatory protein of the homeodomain class. The size of the meristem is thought to be controlled by a self-regulating balance between a short-range stimulatory signal produced by cells expressing Wuschel (*yellow arrow*), and a longer-range inhibitory signal delivered by Clavata3 (*red bars*).

Figure 21-122. Homeotic selector gene expression in an *Arabidopsis* flower. (A) Diagram of the normal expression patterns of the three genes whose mutant phenotypes are illustrated in [Figure 21-121A-C](#). All three genes code for gene regulatory proteins. The colored shading on the flower indicates which organ develops from each whorl of the meristem, but does not imply that the homeotic selector genes are still expressed at this stage. (B) The patterns in a mutant where the *apetala3* gene is defective. Because the character of the organs in each whorl is defined by the set of homeotic selector genes that they express, the stamens and petals are converted into sepals and carpels. The consequence of a deficiency of a gene of class A, such as *apetala2*, is slightly more complex: the absence of this class A gene product allows the class C gene to be expressed in the outer two whorls as well as the inner two, causing these outer whorls to develop as carpels and stamens, respectively. Deficiency of a class C gene prevents the central region from undergoing terminal differentiation as a carpel and causes it instead to continue growth as a meristem, generating more and more sepals and petals.

21-1. Features of Early Development in Flowering Plants

THE FLOWER

Flowers, which contain the reproductive cells of higher plants, arise from vegetative shoot apical meristems (see Figures 21-115 and 21-122). They terminate further vegetative growth from that meristem. Environmental factors, often the rhythms of day length and temperature, trigger the switch from vegetative to floral development. The germ cells thus arise late in plant development from somatic cells rather than from a germ cell line, as in animals.

Flower structure is both varied and species-specific but generally comprises four concentrically arranged sets of structures that may each be regarded as modified leaves.

Petal: distinctive leaflike structures, usually brightly colored, facilitate pollination via, for example, attracted insects.

Stamen: an organ containing cells that undergo meiosis and form haploid pollen grains, each of which contains two male sperm cells. Pollen transferred to a stigma germinates, and the pollen tube delivers the two nonmotile sperm to the ovary.

Carpel: an organ containing one or more ovaries, each of which contains ovules. Each ovule houses cells that undergo meiosis and form an embryo sac containing the female egg cell. At fertilization, one sperm cell fuses with the egg cell and will form the future diploid embryo, while the other fuses with two cells in the embryo sac to form the triploid endosperm tissue.

Sepals: leaflike structures that form a protective covering during early flower development.

THE SEED

A seed contains a dormant embryo, a food store, and a seed coat. By the end of

its development a seed's water content can drop from 90% to 5%. The seed is usually protected in a *fruit* whose tissues are of maternal origin.

The fertilized egg within the ovule will grow to form an embryo using nutrients transported from the endosperm by the suspensor. A complex series of cell divisions, illustrated here for the common weed called shepherd's purse, produces an embryo with a root apical meristem, a shoot apical meristem, and either one (monocots) or two (dicots) seed leaves, called cotyledons.

Development is arrested at this stage, and the ovule, containing the embryo, now becomes a seed, adapted for dispersal and survival.

For the embryo to resume its growth the seed must germinate, a process dependent upon both internal factors (dormancy) and environmental factors including water, temperature, and oxygen. The food reserves for the early phase of germination may either be the endosperm (maize) or the cotyledons (pea and bean).

The primary root usually emerges first from the seed to ensure an early water supply for the seedling. The cotyledon(s) may appear above the ground, as in the garden bean shown here, or they may remain in the soil, as in peas. In both cases the cotyledons eventually wither away.

The apical meristem can now show its capacity for continuous growth, producing a typical pattern of nodes, internodes, and buds (see Figure 21-106).

21-2. The Cell Types and Tissues From Which Higher Plants Are Constructed

THE THREE TISSUE SYSTEMS

Cell division, growth, and differentiation give rise to tissue systems with specialized functions.

DERMAL TISSUE (blue): This is the plant's protective outer covering in contact with the environment. It facilitates water and ion uptake in roots and regulates gas exchange in leaves and stems.

VASCULAR TISSUE: Together the phloem (green) and the xylem (red) form a continuous vascular system throughout the plant. This tissue conducts water and solutes between organs and also provides mechanical support.

GROUND TISSUE (yellow): This packing and supportive tissue accounts for much of the bulk of the young plant. It also functions in food manufacture and storage.

The young flowering plant shown on the *right* is constructed from three main types of organs: leaves, stems, and roots. Each plant organ in turn is made from three tissue systems: ground (yellow), dermal (blue), and vascular (green).

All three tissue systems derive ultimately from the cell proliferative activity of the shoot or root apical meristems, and each contains a relatively small number of specialized cell types. These three common tissue systems, and the cells that comprise them, are described in this panel.

GROUND TISSUE

The ground tissue system contains three main cell types called parenchyma, collenchyma, and sclerenchyma.

Parenchyma cells are found in all tissue systems. They are living cells, generally capable of further division, and have a thin primary cell wall. These cells have a variety of functions. The apical and lateral meristematic cells of shoots and roots provide the new cells required for growth. Food production and storage occur in the photosynthetic cells of the leaf and stem (called mesophyll cells); storage parenchyma cells form the bulk of most fruits and vegetables. Because of their proliferative capacity, parenchyma cells also serve as stem cells for wound healing and regeneration.

A transfer cell, a specialized form of the parenchyma cell, is readily identified by elaborate ingrowths of the primary cell wall. The increase in the area of the plasma membrane beneath these walls facilitates the rapid transport of solutes to and from cells of the vascular system.

root apical meristem

Collenchyma are living cells similar to parenchyma cells except that they have much thicker cell walls and are usually elongated and packed into long ropelike fibers. They are capable of stretching and provide mechanical support in the ground tissue system of the elongating regions of the plant. Collenchyma cells are especially common in subepidermal regions of stems.

typical locations of supporting groups of cells in a stem

sclerenchyma fibers
vascular bundle
collenchyma

Sclerenchyma, like collenchyma, have strengthening and supporting functions. However, they are usually dead cells with thick, lignified secondary cell walls that prevent them from stretching as the plant grows. Two common types are fibers, which often form long bundles, and sclereids, which are shorter branched cells found in seed coats and fruit.

DERMAL TISSUE

The epidermis is the primary outer protective covering of the plant body. Cells of the epidermis are also modified to form stomata and hairs of various kinds.

Epidermis

Stomata

Hairs (or trichomes) are appendages derived from epidermal cells. They exist in a variety of forms and are commonly found in all plant parts. Hairs function in protection, absorption, and secretion; for example,

Go

This book
All books
PubMed

The epidermis (usually one layer of cells deep) covers the entire stem, leaf, and root of the young plant. The cells are living, have thick primary cell walls, and are covered on their outer surface by a special cuticle with an outer waxy layer. The cells are tightly interlocked in different patterns.

Stomata are openings in the epidermis, mainly on the lower surface of the leaf, that regulate gas exchange in the plant. They are formed by two specialized epidermal cells called *guard cells*, which regulate the diameter of the pore. Stomata are distributed in a distinct species-specific pattern within each epidermis.

young, single-celled hairs in the epidermis of the cotton seed. When these grow, the walls will be secondarily thickened with cellulose to form cotton fibers.

Vascular bundles

Roots usually have a single vascular bundle, but stems have several bundles. These are arranged with strict radial symmetry in dicots, but they are more irregularly dispersed in monocots.

a multicellular secretory hair from a geranium leaf

Single-celled root hairs have an important function in water and ion uptake.

VASCULAR TISSUE

The phloem and the xylem together form a continuous vascular system throughout the plant. In young plants they are usually associated with a variety of other cell types in *vascular bundles*. Both phloem and xylem are complex tissues. Their conducting elements are associated with parenchyma cells that maintain the elements and exchange materials with them. In addition, groups of collenchyma and sclerenchyma cells provide mechanical support.

Phloem

small vessel element in root tip

Xylem

Xylem carries water and dissolved ions in the plant. The main conducting cells are the vessel elements shown here, which are dead cells at maturity that lack a plasma membrane. The cell wall has

been secondarily thickened and heavily lignified. As shown below, its end wall is largely removed, enabling very long, continuous tubes to be formed.

22. Histology: The Lives and Deaths of Cells in Tissues

Cells evolved originally as free-living individuals, but the cells that matter most to us, as human beings, are specialized members of a multicellular community. They have lost features needed for independent survival and acquired peculiarities that serve the needs of the body as a whole. Although they share the same genome, they are spectacularly diverse: more than 200 different cell types are traditionally recognized in the human body (see our web site for a list). These collaborate with one another to form a multitude of different tissues, arranged into organs performing widely varied functions. To understand them, it is not enough to analyze them in a culture dish: we need also to know how they live, work, and die in their natural habitat.

In [Chapters 7](#) and [21](#), we saw how the various cell types become different in the embryo and how cell memory and signals from their neighbors enable them to remain different thereafter. In [Chapter 19](#), we discussed the building technology of multicellular tissues—the devices that bind cells together and the extracellular materials that give them support. In this chapter, we consider the functions and lifestyles of the specialized cells in the adult body of a vertebrate. We describe how cells work together to perform their tasks, how new specialized cells are born, how they live and die, and how the architecture of tissues is preserved despite the constant replacement of old cells by new.

We examine these topics through a series of examples—some chosen because they illustrate important general principles, others because they highlight favorite objects of study, still others because they pose intriguing problems that cell biology has yet to solve. [↑ TOP](#)

Histology: The Lives and Deaths of Cells in Tissues

Epidermis and Its Renewal by Stem Cells

To support its specialized functions, the skin has basic requirements that must be satisfied for almost every tissue. It needs mechanical strength, largely provided by a supporting framework of extracellular matrix, mainly secreted by *fibroblasts*. It needs a blood supply to bring nutrients and oxygen and remove waste products and carbon dioxide, and this requires a network of blood vessels, lined with *endothelial cells*. These vessels also provide access routes for cells of the immune system to provide defenses against infection: *macrophages* and *dendritic* cells phagocytose invading pathogens and help activate lymphocytes, which mediate more sophisticated adaptive immune system responses (discussed in [Chapter 24](#)). *Nerve fibers* are needed too, to convey sensory information from the tissue to the central nervous system, and to deliver signals in the opposite direction for glandular secretion and smooth muscle contraction.

[Figure 22-1](#) illustrates the architecture of the tissue and shows how it makes provision for all these support services. Skin consists of two main parts: an epithelium, the *epidermis*, lying outermost, and beneath this a layer of connective tissue, which includes the tough collagen-rich *dermis* (from which leather is made) and the underlying fatty *subcutaneous layer* or *hypodermis*. In the skin, as elsewhere, the connective tissue, with vessels and nerves running through it, is responsible for most of the general supportive functions listed above.

The defining component of the skin—the specialized tissue that is peculiar to this organ, even though not the major part of its bulk—is the epidermis. This has a simple organization, and it provides a beautiful introduction to the way in which tissues of the adult body are continually renewed, through processes similar to those that operate in the embryo. We return to connective tissues later.

Epidermal Cells Form a Multilayered Waterproof Barrier

The epidermis suffers more direct, frequent, and damaging encounters with the external world than any other tissue in the body. Its need for repair and

renewal is central to its organization.

The epidermis is a multilayered (*stratified*) epithelium composed largely of *keratinocytes* (so named because their characteristic differentiated activity is the synthesis of intermediate filament proteins called keratins, which give the epidermis its toughness) (Figure 22-2). These cells change their appearance from one layer to the next. Those in the innermost layer, attached to an underlying basal lamina, are termed *basal cells*, and it is usually only these that divide. Above the basal cells are several layers of larger prickle cells (Figure 22-3), whose numerous desmosomes—each a site of anchorage for thick tufts of keratin filaments—are just visible in the light microscope as tiny prickles around the cell surface (hence the name). Beyond the prickle cells lies the thin, darkly staining granular cell layer (see Figure 22-2). It is at this level that the cells are sealed together to form a waterproof barrier, fulfilling the most fundamentally important of all the functions of the epidermis. Mice that fail to form this barrier because of a genetic defect die from rapid fluid loss soon after birth, even though their skin appears normal in other respects.

The granular layer, with its barrier to the movement of water and solutes, marks the boundary between the inner, metabolically active strata and the outermost layer of the epidermis, consisting of dead cells whose intracellular organelles have disappeared. These outermost cells are reduced to flattened scales, or *squames*, filled with densely packed keratin. The plasma membranes of both the squames and the outer granular cells are reinforced on their cytoplasmic surface by a thin (12 nm), tough, cross-linked layer of proteins, including a cytoplasmic protein called involucrin. The squames themselves are normally so compressed and thin that their boundaries are hard to make out in the light microscope, but soaking in sodium hydroxide solution (or a warm bath tub) makes them swell slightly, and their outlines can then be seen (see Figure 22-2). [↑ TOP](#)

Differentiating Epidermal Cells Synthesize a Sequence of Different Keratins as They Mature

Having described the static picture, let us now set it in motion and see how the epidermis is continually renewed by the production of new cells in the basal layer. While some basal cells are dividing, adding to the population in the basal layer, others (their sisters or cousins) are slipping out of the basal cell layer into the prickle cell layer, taking the first step on their outward journey. When they reach the granular layer, the cells start to lose their nucleus and cytoplasmic organelles, through a degradative mechanism that involves partial activation of the machinery of apoptosis; in this way, the cells are transformed into the keratinized squames of the keratinized layer. These finally flake off from the surface of the skin (and become a main constituent of household dust). The period from the time a cell is born in the basal layer of the human skin to the time it is shed from the surface is of the order of a month, depending on the region of the body.

The accompanying molecular transformations can be studied by analyzing either thin slices of epidermis cut parallel to the surface or successive layers of cells stripped off by repeatedly applying and removing strips of adhesive tape. The keratin molecules, for example, which are plentiful in all layers of the epidermis, can be extracted and characterized. They are of many types (discussed in [Chapter 16](#)), encoded by a large family of homologous genes, with the variety further increased through alternative RNA splicing. As the new keratinocyte in the basal layer is transformed into the squame in the outermost layers (see [Figure 22-3](#)), it switches from one selection of keratins to another. Meanwhile other characteristic proteins, such as involucrin, also begin to be synthesized as part of a coordinated program of **terminal cell differentiation**—the process in which a precursor cell acquires its final specialized characteristics and usually permanently stops dividing. The whole program is initiated in the basal layer. It is here that the fates of the cells are decided. [↑ TOP](#)

Epidermis Is Renewed by Stem Cells Lying in Its Basal Layer

The outer layers of the epidermis are replaced a thousand times over in the course of a human lifetime. In the basal layer there have to be cells that can remain undifferentiated and carry on dividing for this whole period, continually throwing off descendants that differentiate, leave the basal layer, and are eventually discarded. The process can be maintained only if the basal cell population is self-renewing. It must therefore contain some cells that generate a mixture of progeny, including daughters that remain undifferentiated like their parent, as well as daughters that differentiate. Cells with this property are called stem cells. They have so important a role in such a variety of tissues that it is useful to have a formal definition.

The defining properties of a stem cell are as follows:

1. It is not itself terminally differentiated (that is, it is not at the end of a pathway of differentiation).
2. It can divide without limit (or at least for the lifetime of the animal).
3. When it divides, each daughter has a choice: it can either remain a stem cell, or it can embark on a course that commits it to terminal differentiation ([Figure 22-4](#)).

Although it is part of the definition of a stem cell that it should be able to divide, it is not part of the definition that it should divide rapidly; in fact, stem cells usually divide at a relatively low rate. They are required wherever there is a recurring need to replace differentiated cells that cannot themselves divide,

and this includes a great variety of tissues. Thus stem cells are of many types, specialized for the genesis of different classes of terminally differentiated cells—epidermal stem cells for epidermis, intestinal stem cells for intestinal epithelium, hemopoietic stem cells for blood, and so on. Each stem-cell system nevertheless raises similar fundamental questions. What factors determine whether the stem cell divides or stays quiescent? What decides whether a given daughter cell differentiates or remains a stem cell? And where the stem cell can give rise to more than one kind of differentiated cell—as is very often the case—what determines which differentiation pathway is followed? [↑ TOP](#)

The Two Daughters of a Stem Cell Do Not Always Have to Become Different

At steady state, to maintain a stable stem-cell population, precisely 50% of the daughters of stem cells in each cell generation must remain as stem cells. In principle, this could be achieved in two ways—through *environmental asymmetry* or through *divisional asymmetry* (Figure 22-5). In the one strategy, the division of a stem cell could generate two initially similar daughters whose fates would be governed by their subsequent environment; 50% of the *population* of daughters would remain as stem cells, but the two daughters of an individual stem cell in the population might often have the same fate. At the opposite extreme, the stem cell division could be always strictly asymmetric, producing one daughter that inherits the stem-cell character and another that inherits factors that force it to embark on differentiation. In the latter case, the existing stem cells could never increase their numbers, and any loss of stem cells would be irreparable.

In fact, if a patch of epidermis is destroyed, the damage is repaired by surrounding epidermal cells that migrate in and proliferate to cover the denuded area. In this process, a new self-renewing patch of epidermis is established, implying that additional stem cells have been generated to make up for the loss. These must have been produced by symmetric divisions in which one stem cell gives rise to two. In this way, the stem cell population adjusts its numbers to fit the available niche.

Observations such as these suggest that the maintenance of stem cell character in the epidermis might be controlled by contact with the basal lamina, with a loss of contact triggering the start of terminal differentiation, and maintenance of contact tending to preserve stem cell potential. This idea contains a grain of truth, but it is not the whole truth, as we now explain. [↑ TOP](#)

The Basal Layer Contains Both Stem Cells and Transit Amplifying Cells

Basal keratinocytes can be dissociated from intact epidermis and can proliferate in a culture dish, giving rise to new basal cells and to terminally

differentiated cells. Even within a population of cultured basal keratinocytes that all seem undifferentiated, there is great variation in the ability to proliferate. When cells are taken singly and tested for their ability to found new colonies, some seem unable to divide at all, others go through only a few division cycles and then halt, and still others divide enough times to form large colonies. This proliferative potential directly correlates with the expression of the $\beta 1$ subunit of integrin (see [Figure 19-64](#)). Clusters of cells with high levels of this molecule can be found in the basal layer of the intact human epidermis also, and they are thought to be the stem cells ([Figure 22-6](#)).

Basal cells expressing $\beta 1$ integrin at a lower level can also divide—indeed, they divide more frequently—but only for a limited number of division cycles, after which they leave the basal layer and differentiate. These latter cells are called **transit amplifying cells**—"transit", because they are in transit from a stem-cell character to a differentiated character; "amplifying", because the division cycles they go through have the effect of amplifying the number of differentiated progeny that result from a single stem-cell division ([Figure 22-7](#)). Mingled with the population of transit amplifying cells are some cells, still connected with the basal lamina by a thin stalk, that have already stopped dividing and begun to differentiate, as indicated by the types of keratin molecules they express. Contact with the basal lamina, therefore, cannot be the only factor controlling the developmental fate of an epidermal basal cell.

This is not to say that contact with the basal lamina or a similar substratum does not matter. If cultured basal keratinocytes are held in suspension, instead of being allowed to settle and attach to the bottom of the culture dish, they all stop dividing and differentiate. To remain as an epidermal stem cell, it is apparently necessary for it to be attached to the basal lamina or other extracellular matrix, even though it is not sufficient. This requirement helps ensure that the size of the stem cell population does not increase without limit. If crowded out of their regular niche on the basal lamina, the cells lose their stem cell character. When this rule is broken, as in some cancers, the result can be an ever-growing tumor. [↑ TOP](#)

Epidermal Renewal Is Governed by Many Interacting Signals

Cell turnover in the epidermis seems at first glance a simple matter, but the simplicity, as we have just seen, is deceptive. There are many points in the process that have to be controlled according to circumstances: the rate of stem-cell division; the probability that a stem-cell daughter will remain a stem cell; the number of cell divisions of the transit amplifying cells; the timing of exit from the basal layer, and the time that the cell then takes to complete its differentiation program and be sloughed from the surface. Regulation of these steps must enable the epidermis to respond to rough usage by becoming thick and callused, and to repair itself when wounded. In specialized regions of epidermis, such as those that form hair follicles, with their own specialized

subtypes of stem cells, yet more controls are needed to organize the local pattern.

Each control point is important in its own way, and a whole panoply of molecular signals regulate them, so as to keep the body surface always properly covered. Most of the cell communication mechanisms described in [Chapter 15](#) are implicated, either in signaling between cells within the epidermis or in signaling between epidermis and dermis. The EGF, FGF, Wnt, Hedgehog, Notch, BMP/TGF β , and integrin signaling pathways are all involved (and we shall see that the same is true of most other tissues). Mutations in components of the Hedgehog or Wnt pathways, for example, can lead to the development of epidermal cancers. Components of the Hedgehog, Notch, BMP, and Wnt pathways when misexpressed interfere with the formation of hairs, blocking their development or causing them to develop out of place.

Activation of the Wnt pathway seems to favor maintenance of stem-cell character, inhibiting the switch from stem cell to transit amplifying cell, whereas Notch signaling in the epidermis seems to have a contrary effect, inhibiting neighbors of stem cells from remaining as stem cells. TGF β has a key role in signaling to the dermis during the repair of skin wounds, promoting the formation of collagen-rich scar tissue. And integrins in the epidermis are not merely markers of cell character, but also regulators of cell fate. Thus, when transgenic mice are engineered to maintain in upper epidermal layers the expression of integrins normally confined to the basal layer, they develop a condition resembling the common human skin disorder *psoriasis*: the rate of basal cell proliferation is greatly increased, the epidermis thickens, and cells are shed from the surface of the skin within as little as a week after emerging from the basal layer, before they have had time to keratinize fully. The precise individual functions of all the various signaling mechanisms in the epidermis are only beginning to be disentangled. [↑ TOP](#)

The Mammary Gland Undergoes Cycles of Development and Regression

In specialized regions of the body surface, other types of cells besides the keratinized cells described above develop from the embryonic epidermis. In particular, secretions such as sweat, tears, saliva, and milk are produced by cells segregated in deep-lying glands that originate as ingrowths of the epidermis. These epithelial structures have functions and patterns of renewal quite different from those of keratinizing regions.

The mammary glands are the largest and most remarkable of these secretory organs. They are the defining feature of mammals and an important concern in many ways: not only for nourishment of babies and attraction of the opposite sex, but also as the basis for a large industry—the dairy industry—and as the site of some of the commonest forms of cancer. Mammary tissue illustrates

most dramatically that developmental processes continue in the adult body; and it shows how cell death by apoptosis can allow development to go into reverse.

Milk production must be switched on when a baby is born and switched off when the baby is weaned. A "resting" adult mammary gland consists of branching systems of ducts embedded in fatty connective tissue. The ducts are lined by an epithelium that includes a subpopulation of mammary stem cells (though the precise location of the stem cells is still debated). As a first step toward milk production, the hormones that circulate during pregnancy cause the duct cells to proliferate, increasing their numbers tenfold or twentyfold. The terminal portions of the ducts grow and branch, forming little dilated outpocketings, or alveoli, containing secretory cells ([Figure 22-8](#)). Milk secretion begins only when these cells are stimulated by the different combination of hormones that circulate in the mother after the birth of the baby. A further tier of hormonal control governs the actual ejection of milk from the breast: the stimulus of suckling causes cells of the hypothalamus (in the brain) to release the hormone *oxytocin*, which travels via the bloodstream to act on *myoepithelial cells*. These musclelike cells originate from the same epithelial precursor population as the secretory cells of the breast, and they have long spidery processes that embrace the alveoli. In response to oxytocin they contract, thereby squirting milk out of the alveoli into the ducts.

Eventually, when the baby is weaned and suckling stops, the secretory cells die by apoptosis, and most of the alveoli disappear. Macrophages rapidly clear away the dead cells, and the gland reverts to its resting state. This ending of lactation is abrupt and, unlike the events that lead up to it, seems to be induced by the accumulation of milk, rather than by a hormonal mechanism. If one subset of mammary ducts is obstructed so that no milk can be discharged, the secretory cells that supply it commit mass suicide by apoptosis, while other regions of the gland survive and continue to function. The apoptosis is triggered by a combination of factors including TGF β 3, which accumulates where milk secretion is blocked ([Figure 22-9](#)).

Cell division in the growing mammary gland is regulated not only by hormones but also by local signals passing between cells within the epithelium and between the epithelial cells and the connective tissue, or *stroma*, in which the epithelial cells are embedded. All the signals listed earlier as important in controlling cell turnover in the epidermis are also implicated in controlling events in the mammary gland. Again, signals delivered via integrins play a crucial part: deprived of the basal lamina adhesions that activate integrin signaling, the epithelial cells fail to respond normally to hormonal signals. Faults in these interacting control systems underlie some of the commonest forms of cancer, and we need to understand them better. [↑ TOP](#)

Summary

Skin consists of a tough connective tissue, the dermis, overlaid by a multilayered waterproof epithelium, the epidermis. The epidermis is continually renewed from stem cells, with a turnover time, in humans, of the order of a month. Stem cells, by definition, are not terminally differentiated and have the ability to divide throughout the lifetime of the organism, yielding some progeny that differentiate and others that remain stem cells. The epidermal stem cells lie in the basal layer, attached to the basal lamina. Progeny that become committed to differentiation go through several rapid divisions in the basal layer, and then stop dividing and move out toward the surface of the skin. They progressively differentiate, switching from expression of one set of keratins to expression of another until, eventually, their nuclei degenerate, producing an outer layer of dead keratinized cells that are continually shed from the surface.

The fate of the daughters of a stem cell is controlled in part by interactions with the basal lamina and in part by a variety of signals from neighboring cells. These controls allow two stem cells to be generated from one during repair processes, and they regulate the rate of basal cell proliferation according to need. Glands connected to the epidermis, such as the mammary glands, have their own stem cells and their own distinct patterns of cell turnover, governed by other conditions. In the breast, for example, circulating hormones stimulate the cells to proliferate, differentiate, and make milk; the cessation of suckling triggers the milk-secreting cells to die by apoptosis, as a result of a build-up of TGF β 3 where milk fails to be drained away. Figure 22-2. The multilayered structure of the epidermis, as seen in a mouse. The outlines of the keratinized squames are revealed by swelling them in a solution containing sodium hydroxide. The highly ordered hexagonal arrangement of interlocking columns of cells shown here occurs only in some sites where the epidermis is thin. In human skin, the stacks of squames are usually many times higher and less regular, and where the skin is very thick mitotic cells are seen not only in the basal layer but also in the first few cell layers above it. In addition to the cells destined for keratinization, the deep layers of the epidermis include small numbers of cells of different characters, as indicated in [Figure 21-1](#)—including dendritic cells, called Langerhans cells, derived from bone marrow; melanocytes (pigment cells) derived from the neural crest; and Merkel cells, which are associated with nerve endings in the epidermis.

Figure 22-6. The distribution of stem cells in human epidermis, and the pattern of epidermal cell production. The diagram is based on specimens in which the location of the stem cells was identified by staining for $\beta 1$ -integrin, and that of the differentiating cells by staining for keratin-10, a marker of keratinocyte differentiation; dividing cells were identified by labeling with BrdU, a thymidine analog that is incorporated into cells in S-phase of the cell division cycle. The stem cells seem to be clustered near the tips of the dermal papillae. They divide infrequently, giving rise (through a sideways movement) to transit amplifying cells, which occupy the intervening regions. The transit amplifying cells divide frequently, but for a limited number of division cycles, at the end of which they begin to differentiate and slip out of the basal layer. The precise distribution of stem cells and transit amplifying cells varies from one region of epidermis to another. (Adapted from S. Lowell et al., *Curr. Biol.* 10:491–500, 2000.)

Figure 22-7. Transit amplifying cells. Stem cells in many tissues divide only rarely, but give rise to transit amplifying cells—daughters committed to differentiation that go through a limited series of more rapid divisions before completing the process. In the example shown here, each stem cell division gives rise in this way to eight terminally differentiated progeny.

Figure 22-8. The mammary gland. (A) The growth of alveoli from the ducts of the mammary gland during pregnancy and lactation. Only a small part of the gland is shown. The "resting" gland contains a small amount of inactive glandular tissue embedded in a large amount of fatty connective tissue. During pregnancy an enormous proliferation of the glandular tissue takes place at the expense of the fatty connective tissue, with the secretory portions of the gland developing preferentially to create alveoli. (B) One of the milk-secreting alveoli with a basket of contractile myoepithelial cells (*green*) embracing it (see also Figure 22-40E). (C) A single type of secretory alveolar cell produces both the milk proteins and the milk fat. The proteins are secreted in the normal way by exocytosis, while the fat is released as droplets surrounded by plasma membrane detached from the cell. (B, after R. Krsti'c, *Die Gewebe des Menschen und der Säugetiere*. Berlin: Springer-Verlag, 1978; C, from D.W. Fawcett, *A Textbook of Histology*, 12th edn. New York: Chapman and Hall, 1994.)

Histology: The Lives and Deaths of Cells in Tissues

Sensory Epithelia

It is through another class of specializations of the epithelium covering our body surface that we sense the smells, sounds and sights of the external world. The sensory tissues of the nose, the ears, and the eyes—and, indeed, if we look back to origins in the early embryo, the whole of the central nervous system—all arise as parts of the same sheet of cells, the *ectoderm*, that gives rise to the epidermis (see [Chapter 21](#)). These structures have several basic features in common, and their development is governed by related systems of genes (discussed in [Chapter 21](#)). They all retain an epithelial organization, but it is very different from that of the ordinary epidermis or of the glands that derive from it.

The nose, the ear, and the eye are complex organs, with elaborate devices to collect signals from the external world and to deliver them, filtered and concentrated, to the sensory epithelia, where they can trigger effects on the nervous system. The sensory epithelium in each organ is the key component, although it is small relative to all the ancillary apparatus. It is the part that has been most highly conserved in evolution, not only from one vertebrate to another, but also between vertebrates and invertebrates.

Within each sensory epithelium lie sensory cells that act as *transducers*, converting signals from the outside world into an electrical form that can be interpreted by the nervous system. In the nose, the sensory transducers are *olfactory sensory neurons*; in the ear, *auditory hair cells*; and in the eye, *photoreceptors*. All of these cell types are either neurons or neuron-like. Each carries at its apical end a specialized structure that detects the external stimulus and converts it to a change in the membrane potential. At its basal end, each makes synapses with neurons that relay the sensory information to specific sites in the brain.

Olfactory Sensory Neurons Are Continually Replaced

In the olfactory epithelium of the nose ([Figure 22-10A](#)), a subset of the epithelial cells differentiate as **olfactory sensory neurons**. These cells have modified, immotile cilia on their free surfaces (see [Figure 15-43](#)), containing

 [Figure 22-10. Olfactory epithelium and olfactory neurons.](#)

 [Figure 22-16. Turnover of membrane protein in...](#)

odorant receptor proteins, and a single axon extending from their basal end towards the brain ([Figure 22-10B](#)). The neurons are held in place and separated from one another by *supporting cells* that span the thickened epithelium and have properties similar to those of glial cells in the central nervous system. The sensory surfaces are kept moist and protected by a layer of fluid secreted by cells sequestered in glands that communicate with the exposed surface. Even with this protection, however, each olfactory neuron survives for only a month or two, and so a third class of cells—the *basal cells*—is present in the epithelium to generate replacements for the olfactory neurons that are lost. The basal cells are stem cells for the production of the neurons.

As discussed in [Chapter 15](#), each olfactory neuron expresses most probably only one of the hundreds of odorant receptor genes in the genome. This determines which odorants the cell responds to. But regardless of the odor, the response of every olfactory neuron is the same—a train of action potentials sent back along its axon to the brain. The discriminating sensibility of an individual olfactory neuron is therefore useful only if its axon delivers its messages to the specific relay station in the brain that is dedicated to the particular range of odors that the neuron senses. These relay stations are called *glomeruli*. They are located in structures called the olfactory bulbs (one on each side of the brain), with about 1800 glomeruli in each bulb (in the mouse). Olfactory neurons expressing the same odorant receptor are widely scattered in the olfactory epithelium, but their axons all converge on the same glomerulus ([Figure 22-10C](#)). As new olfactory neurons are generated, replacing those that die, they must in turn send their axons to the correct glomerulus. The odorant receptor proteins thus have been proposed to have a second function: helping to guide the growing tips of the new axons along specific paths to the appropriate target glomeruli in the olfactory bulbs. If it were not for the continual operation of this guidance system, a rose might smell in one month like a lemon, in the next like rotting fish. [↑ TOP](#)

Auditory Hair Cells Have to Last a Lifetime

The sensory epithelium responsible for hearing is the most precisely and minutely engineered of all the tissues in the body ([Figure 22-11](#)). Its sensory cells, the **auditory hair cells**, are held in a rigid framework of supporting cells and overlaid by a mass of extracellular matrix (the tectorial membrane), in a structure called the *organ of Corti*. The hair cells convert mechanical stimuli into electrical signals. Each has a characteristic organ-pipe array of giant microvilli (called *stereocilia*) protruding from its surface as rigid rods, filled with cross-linked actin filaments, and arranged in ranks of graded height. The dimensions of each such array are specified with extraordinary accuracy according to the location of the hair cell in the ear and the frequency of sound that it has to respond to. Sound vibrations rock the organ of Corti, causing the bundles of stereocilia to tilt ([Figure 22-12](#)) and mechanically gated ion channels in the membranes of the stereocilia to open or close ([Figure 22-13](#)). The flow of electric charge carried into the cell by the ions alters the

membrane potential and thereby controls the release of neurotransmitter at the cell's basal end, where the cell synapses with a nerve ending.

In humans and other mammals, the auditory hair cells, unlike olfactory neurons, have to last a lifetime. If they are destroyed by disease, toxins, or excessively loud noise, they are not regenerated and the resultant hearing loss is permanent. But in other vertebrates, when auditory hair cells are destroyed, the supporting cells are triggered to divide and behave as stem cells, generating progeny that can differentiate as replacements for the hair cells that are lost. With better understanding of how this regeneration process is regulated, we may one day be able to induce the auditory epithelium to repair itself in humans also. [↑ TOP](#)

Most Permanent Cells Renew Their Parts: the Photoreceptor Cells of the Retina

The neural retina is the most complex of the sensory epithelia. It consists of several cell layers organized in a way that seems perverse. The neurons that transmit signals from the eye to the brain (called *retinal ganglion cells*) lie closest to the external world, so that the light, focused by the lens, must pass through them to reach the photoreceptor cells. The photoreceptors, which are classified as *rods* or *cones*, according to their shape, lie with their photoreceptive ends, or outer segments, partly buried in the *pigment epithelium* ([Figure 22-14](#)). Rods and cones contain different *rhodopsins*—photosensitive complexes of *opsin* protein with the visual pigment *retinal*. Rods are especially sensitive at low light levels, while cones (of which there are three types, each with a different opsin, giving a different spectral response) detect color and fine detail.

The outer segment of a photoreceptor appears to be a modified cilium with a characteristic ciliumlike arrangement of microtubules in the region where the outer segment is connected to the rest of the cell ([Figure 22-15](#)). The remainder of the outer segment is almost entirely filled with a dense stack of membranes in which the photosensitive complexes are embedded; light absorbed here produces an electrical response, as discussed in [Chapter 15](#). At their opposite ends, the photoreceptors form synapses on interneurons, which relay the signal to the retinal ganglion cells (see [Figure 22-14](#)).

Photoreceptors in humans, like human auditory hair cells, are permanent cells that do not divide and are not replaced if destroyed by disease or by a mis-directed laser beam. But the photosensitive rhodopsin molecules are not permanent but are continually degraded and replaced. In rods (although not, curiously, in cones), this turnover is organized in an orderly production line, which can be analyzed by following the passage of a cohort of radiolabeled protein molecules through the cell after a short pulse of radioactive amino acid ([Figure 22-16](#)). The radiolabeled proteins can be followed from the Golgi apparatus in the inner segment of the cell to the base of the stack of

membranes in the outer segment. From here they are gradually displaced toward the tip as new material is fed into the base of the stack. Finally (after about 10 days in the rat), on reaching the tip of the outer segment, the labeled proteins and the layers of membrane in which they are embedded are phagocytosed (chewed off and digested) by the cells of the pigment epithelium.

This example illustrates a general point: even though individual cells of certain types persist, very little of the adult body consists of the same molecules that were laid down in the embryo. [↑ TOP](#)

Summary

Most sensory receptor cells, like epidermal cells and nerve cells, derive from the epithelium forming the outer surface of the embryo. They transduce external stimuli into electrical signals, which they relay to neurons via chemical synapses. Olfactory receptor cells in the nose are themselves full-fledged neurons, sending their axons to the brain. They have a lifetime of only a month or two, and are continually replaced by new cells derived from stem cells in the olfactory epithelium. Each olfactory neuron expresses just one of the hundreds of different olfactory receptor proteins for which genes exist in the genome, and the axons from all olfactory neurons expressing the same receptor protein navigate to the same glomeruli in the olfactory bulbs of the brain.

Auditory hair cells—the receptor cells for sound—unlike olfactory receptor cells, have to last a lifetime, in mammals at least. They have no axon but make synaptic contact with nerve terminals in the auditory epithelium. They take their name from the hair-like bundle of stereocilia (giant microvilli) on their outer surface. Sound vibrations tilt the bundle, pulling mechanically gated ion channels on the stereocilia into an open configuration to excite the cell electrically.

Photoreceptor cells in the retina of the eye absorb photons in rhodopsin molecules held in stacks of membrane in the photoreceptor outer segments, triggering an electrical excitation by a more indirect intracellular signaling pathway. Although the photoreceptor cells themselves are permanent and irreplaceable, the stacks of rhodopsin-rich membrane that they contain undergo continual renewal. [↑ TOP](#)

Figure 22-10. Olfactory epithelium and olfactory neurons. (A) Olfactory epithelium consists of supporting cells, basal cells, and olfactory sensory neurons. The basal cells are the stem cells for production of the olfactory neurons. Six to eight modified cilia project from the apex of the olfactory neuron and contain the odorant receptors. (B) This micrograph shows olfactory neurons in the nose of a genetically modified mouse in which the gene encoding LacZ has been inserted into an odorant receptor locus, so that all the cells that would normally express that particular receptor now make the enzyme LacZ in addition. The LacZ is detected through the blue product of the enzymatic reaction that it catalyzes. The cell bodies (*dark blue*) of the marked olfactory neurons, lying scattered in the olfactory epithelium, send their axons (*light blue*) toward the brain (out of the picture to the *right*). (C) A cross section of the *left* and *right* olfactory bulbs, stained for LacZ. Axons of all the olfactory neurons expressing the same odorant receptor converge on the same glomeruli (*red arrows*) symmetrically placed within the bulbs on the *right* and *left* sides of the brain. Other glomeruli (unstained) receive their inputs from olfactory neurons expressing other odorant receptors. (B and C, from P. Mombaerts et al., *Cell* 87:675–686, 1996. © Elsevier.)

Molecular Biology of the Cell ➔ V. Cells in Their Social Context ➔ 22. Histology: The Lives and Deaths of Cells in Tissues ➔ Sensory Epithelia

Figure 22-13. How a sensory hair cell works. (A) The cell functions as a transducer, generating an electrical signal in response to sound vibrations that rock the organ of Corti and so cause the stereocilia to tilt. A fine filament runs more or less vertically upward from the tip of each shorter stereocilium to attach at a higher point on its adjacent taller neighbor. Tilting the bundle puts tension on the filaments, which pull on mechanically gated ion channels in the membrane of the stereocilia. Opening of these channels allows an influx of positive charge, depolarizing the hair cell. (B) An electron micrograph of the filaments extending from the tops of two stereocilia. By extraordinarily delicate mechanical measurements, correlated with electrical recordings from a single hair cell as the bundle of stereocilia is deflected by pushing with a flexible glass probe, it is possible to detect an extra "give" of the bundle as the mechanically gated channels yield to the applied force and are pulled open. In this way it can be shown that the force required to open a single one of the hypothesized channels is about 2×10^{-13} newtons and that its gate swings through a distance of about 4 nm as it opens. The mechanism is astonishingly sensitive: the faintest sounds that we can hear have been estimated to stretch the filaments by an average of 0.04 nm, which is just under half the diameter of a hydrogen atom. (B, from B. Kachar et al., *Proc. Natl. Acad. Sci. USA* 97:13336–13341, 2000. © National Academy of Sciences.)

Histology: The Lives and Deaths of Cells in Tissues

The Airways and the Gut

The examples we have discussed so far represent a small selection of the tissues and cell types that derive from the outer layer of the embryo—the ectoderm. They are enough, however, to give a sense of the amazing variety of ways in which this epithelium becomes specialized for different purposes, and to show how widely adult cells can differ in their lifestyles. The inmost layer of the embryo—the *endoderm*, forming the primitive gut tube—gives rise to another whole zoo of cell types lining the digestive tract and its appendages. We begin with the lungs.

Adjacent Cell Types Collaborate in the Alveoli of the Lungs

The airways of the lungs are formed by repeated branching of a system of tubes that originated in the embryo from an outpocketing of the gut lining, as discussed in [Chapter 21](#). Repeated tiers of branching terminate in several hundred million air-filled sacs—the **alveoli**. Alveoli have thin walls, closely apposed to the walls of blood capillaries so as to allow exchange of O₂ and CO₂ with the blood stream ([Figure 22-17](#)).

To survive, the cells lining the alveoli must remain moist. At the same time, they must serve as a gas container that can expand and contract with each breath in and out. This creates a problem. When two wet surfaces touch, they become stuck together by surface tension in the layer of water between them—an effect that operates more powerfully the smaller the scale of the structure. There is a risk, therefore, that the alveoli may collapse and be impossible to reinflate. The problem is solved by the presence of two types of cells in the lining of the alveoli. *Type I alveolar cells* cover most of the wall: they are thin and flat (*squamous*) to allow gas exchange. *Type II alveolar cells* are interspersed among them. These are plump and secrete *surfactant*, a phospholipid-rich material that forms a film on the free water surfaces and reduces surface tension, making the alveoli easy to reinflate even if they collapse. The production of adequate amounts of surfactant in the fetus, starting at about 5 months of pregnancy in humans, marks the beginning of the possibility of independent life. Premature babies born before this stage are

unable to inflate their lungs and breathe; those born after it can do so and, with intensive care, can survive. [↑ TOP](#)

Goblet Cells, Ciliated Cells, and Macrophages Collaborate to Keep the Airways Clean

Higher up in the airways one finds different combinations of cell types, serving different purposes. The air we breathe is full of dust, dirt, and air-borne microorganisms. To keep the lungs clear and healthy, this debris must be constantly swept out. To perform this task, the larger airways are lined by a relatively thick *respiratory epithelium* (Figure 22-18). This includes three differentiated cell types: *goblet cells* (so named because of their shape), which secrete mucus, *ciliated cells*, with cilia that beat, and a small number of *endocrine cells*, secreting serotonin and peptides that act as local mediators. These signal molecules affect nerve endings and other neighboring cells in the respiratory tract, so as to help regulate the rate of mucus secretion and ciliary beating, the contraction of surrounding smooth muscle cells that can constrict the airways, and other functions. Basal cells are also present, and serve as stem cells for renewal of the epithelium.

The mucus secreted by the goblet cells forms a viscoelastic blanket about 5 μm thick over the tops of the cilia. The cilia, all beating in the same direction, at a rate of about 12 beats per second, sweep the mucus out of the lungs, carrying with it the debris that has become stuck to it. This conveyor belt for the removal of rubbish from the lungs is called the *mucociliary escalator*. Of course, some inhaled particles may reach the alveoli themselves, where there is no escalator. Here, the unwanted matter is removed by yet another class of specialized cells, *macrophages*, which roam the lungs and engulf foreign matter and kill and digest bacteria. Many millions of macrophages, loaded with debris, are swept out of the lungs every hour on the mucociliary escalator.

At the upper end of the respiratory tract, the wet mucus-covered respiratory epithelium gives way abruptly to stratified squamous epithelium. This cell sheet is structured for mechanical strength and protection, and, like epidermis, it consists of many layers of flattened cells densely packed with keratin. It differs from epidermis in that it is kept moist and its cells retain their nucleus even in the outermost layers. Abrupt boundaries of epithelial cell specialization, such as that between the mucous and the stratified squamous epithelium of the respiratory tract, are also found in other parts of the body, but very little is known about how they are created and maintained. The Lining of the Small Intestine Renews Itself Faster Than Any Other Tissue

Only air-breathing vertebrates have lungs, but all vertebrates, and almost all invertebrate animals, have a gut—that is, a digestive tract lined with cells

specialized for the digestion of food and absorption of the nutrient molecules released by the digestion. These two activities are hard to carry on at the same time, as the processes that digest food in the lumen of the gut are liable also to digest the lining of the gut itself, including the cells that absorb the nutrients. The gut uses several strategies to solve the problem.

The fiercest digestive processes, involving acid hydrolysis as well as enzyme action, are conducted in a separate reaction vessel, the stomach. The products are then passed on to the small intestine, where the nutrients are absorbed and enzymatic digestion continues, but at a neutral pH. The different regions of the gut lining consist of correspondingly different mixtures of cell types. The stomach epithelium includes cells that secrete acid, and other cells that secrete digestive enzymes that work at acid pH. Conversely, glands (in particular the pancreas) that discharge into the initial segment of the small intestine contain cells that secrete bicarbonate to neutralize the acidity, along with other cells that secrete digestive enzymes that work at neutral pH. The lining of the intestine, downstream from the stomach, contains both absorptive cells and cells specialized for secretion of mucus, which covers the epithelium with a protective coat. In the stomach, too, the most exposed surfaces are lined with mucous cells. And, in case these measures are not enough, the whole lining of the stomach and intestine is continually renewed and replaced by freshly generated cells, with a turnover time of a week or less.

The renewal process has been studied best in the small intestine ([Figure 22-19](#)). The lining of the small intestine (and of most other regions of the gut) is a single-layered epithelium. This epithelium covers the surfaces of the *villi* that project into the lumen, and it lines the *crypts* that descend into the underlying connective tissue. Dividing stem cells lie in a protected position in the depths of the crypts. These generate four types of differentiated progeny ([Figure 22-20](#)): (1) *absorptive cells* (also called *brush-border cells*), with densely packed microvilli on their exposed surfaces to increase their active surface area; (2) *goblet cells* (as in respiratory epithelium), secreting mucus; (3) *Paneth cells*, forming part of the innate immune defense system (discussed in [Chapter 25](#)) and secreting (along with some growth factors) *cryptdins*—proteins of the defensin family that kill bacteria (see [Figure 25-39](#)); and (4) *enteroendocrine cells*, of more than 15 different subtypes, secreting serotonin and peptide hormones, such as cholecystokinin, that act on neurons and other cell types in the gut wall and regulate the growth, proliferation and digestive activities of cells of the gut and other tissues; many of these gut hormones function also as neuropeptide signal molecules in the nervous system.

The absorptive, goblet, and enteroendocrine cells travel mainly upward from the stem-cell region, by a sliding movement in the plane of the epithelial sheet, to cover the surfaces of the villi. As in the epidermis, there is a transit amplifying stage of cell proliferation: on their way out of the crypt, the precursor cells, already committed to differentiation, go through four to six rapid divisions before they stop dividing and differentiate terminally. Within

2–5 days (in the mouse) after emerging from the crypts, the cells reach the tips of the villi, where they undergo the initial stages of apoptosis and are finally discarded into the gut lumen. The Paneth cells are produced in much smaller numbers and have a different migration pattern. They stay down at the bottom of the crypts, where they too are continually replaced, although not so rapidly, persisting for about 20 days (in the mouse) before undergoing apoptosis and being phagocytosed by their neighbors.

The driving force for the movements of the gut epithelial cells is still a mystery. Their different patterns of migration may be controlled by cell-type-specific responses to molecular cues in the basal lamina on which they sit. Different regions of the lamina are rich in different types of laminin: $\alpha 1$ and $\alpha 2$ laminin subunits are concentrated in the basal lamina of the crypts, while $\alpha 5$ is in the basal lamina of the villi, in a concentration gradient with its maximum at the villus tip. [↑ TOP](#)

Components of the Wnt Signaling Pathway Are Required to Maintain the Gut Stem-Cell Population

What controls whether a gut stem cell retains its stem-cell character or embarks on differentiation? What drives the diversification of the stem cell progeny to produce four different cell types? Despite their importance in normal life and in many diseases, including common forms of cancer, the answers are unknown. There are, however, some clues.

The production of enteroendocrine cells, for example, depends on a cell-fate choice governed by the Notch signaling pathway in much the same way as the production of neurons in the embryonic central nervous system (discussed in [Chapter 21](#)). Mutations that block Notch signaling cause enteroendocrine cells to be produced in excess at the expense of other cell types, at least in the embryo.

Other experiments indicate that the Wnt signaling pathway has a crucial role in maintaining the stem cell population of the gut. Mice deficient in one of the LEF-1/TCF family of gene regulatory proteins involved in Wnt signaling (discussed in [Chapter 15](#)) provide one line of evidence: villi covered with differentiated cells are formed in the mutant fetus, but the epithelium cannot be renewed, because no crypts form and no proliferating stem cells are retained, and the mouse dies soon after birth. Conversely, in adult life, overactivation of the same signaling pathway by mutations in another gene (the *APC* gene—see [Figure 15-72](#)) result in an overproliferation of crypt cells and frequently lead to cancer, as we shall see in [Chapter 23](#). All this suggests that in the gut, as in the epidermis, Wnt signaling has a key role in either maintaining stem cells as stem cells or controlling their proliferation. [↑ TOP](#)

The Liver Functions as an Interface Between the Digestive

Tract and the Blood

As we have just seen, the functions of the gut are divided between a variety of cell types. Some cells are specialized for the secretion of hydrochloric acid, others for the secretion of enzymes, others for the absorption of nutrients, and so on. Some of these cell types are closely intermingled in the wall of the gut, whereas others are segregated in large glands that communicate with the gut and originate in the embryo as outgrowths of the gut epithelium.

The liver is the largest of these glands. It develops at a site where a major vein runs close to the wall of the primitive gut tube, and the adult organ retains a special relationship with the blood. Cells in the liver that derive from the primitive gut epithelium—the hepatocytes—are arranged in interconnected sheets and cords, with blood-filled spaces called sinusoids running between them (Figure 22-21). The blood is separated from the surface of the hepatocytes by a single layer of flattened endothelial cells that covers the exposed faces of the hepatocytes. This structure facilitates the chief functions of the liver, which center on the exchange of metabolites between hepatocytes and the blood.

The liver is the main site at which nutrients that have been absorbed from the gut and then transferred to the blood are processed for use by other cells of the body. It receives a major part of its blood supply directly from the intestinal tract (via the portal vein). Hepatocytes are responsible for the synthesis, degradation, and storage of a vast number of substances. They play a central part in the carbohydrate and lipid metabolism of the body as a whole, and they secrete most of the protein found in blood plasma. At the same time, the hepatocytes remain connected with the lumen of the gut via a system of minute channels (or canaliculi) and larger ducts (see Figure 22-21B,C) and secrete into the gut by this route both waste products of their metabolism and an emulsifying agent, *bile*, which helps in the absorption of fats. Hepatocytes are big cells, and about 50% of them (in an adult human) are polyploid, with two, four, eight, or even more times the normal diploid quantity of DNA per cell.

In contrast to the rest of the digestive tract, there seems to be remarkably little division of labor within the population of hepatocytes. Each hepatocyte seems able to perform the same broad range of metabolic and secretory tasks. These fully differentiated cells can also divide repeatedly, when the need arises, as we explain next. [↑ TOP](#)

Liver Cell Loss Stimulates Liver Cell Proliferation

The liver illustrates in a striking way one of the great unsolved problems of developmental and tissue biology: what determines the size of an organ of the body, or the quantity of one type of tissue relative to another? For different organs, the answers are almost certainly different, but there is scarcely any case in which the mechanism is well understood.

Hepatocytes normally live for a year or more and are renewed at a slow rate. Even in a slowly renewing tissue, however, a small but persistent imbalance between the rate of cell production and the rate of cell death would lead to disaster. If 2% of the hepatocytes in a human divided each week but only 1% died, the liver would grow to exceed the weight of the rest of the body within 8 years. Homeostatic mechanisms must operate to adjust the rate of cell proliferation and/or the rate of cell death so as to keep the organ at its normal size. This size, moreover, needs to be matched to the size of the rest of the body. Indeed, when the liver of a small dog is grafted into a large dog, it rapidly grows to almost the size appropriate to the host; conversely, when the liver is grafted from a large dog into a small one, it shrinks.

Direct evidence for the homeostatic control of liver cell proliferation comes from experiments in which large numbers of hepatocytes are removed surgically or are intentionally killed by poisoning with carbon tetrachloride. Within a day or so after either sort of damage, a surge of cell division occurs among the surviving hepatocytes, and the lost tissue is quickly replaced. (If the hepatocytes themselves are totally eliminated, another class of cells, located in the bile ducts, can serve as stem cells for the genesis of new hepatocytes, but usually there is no need for this.) If two-thirds of a rat's liver is removed, for example, a liver of nearly normal size can regenerate from the remainder by hepatocyte proliferation within about 2 weeks. Many molecules have been implicated in the triggering of this reaction. One of the most important is a protein called *hepatocyte growth factor*. It stimulates hepatocytes to divide in culture, and its production increases steeply (by poorly understood mechanisms) in response to liver damage.

The balance between cell births and cell deaths in the adult liver (and other organs too) does not depend exclusively on the regulation of cell proliferation: cell survival controls also play a part. If an adult rat is treated with the drug phenobarbital, for example, hepatocytes are stimulated to divide, causing the liver to enlarge. When the phenobarbital treatment is stopped, hepatocyte cell death greatly increases until the liver returns to its original size, usually within a week or so. The mechanism of this type of cell survival control is unknown, but it has been suggested that hepatocytes, like most vertebrate cells, depend on signals from other cells for their survival and that the normal level of these signals can support only a certain standard number of hepatocytes. If the number of hepatocytes rises above this (as a result of phenobarbital treatment, for example), hepatocyte death will automatically increase to bring their number back down. It is not known how the appropriate levels of survival factors are maintained.  [TOP](#)

Summary

The lung performs a simple function—gas exchange—but its housekeeping systems are complex. Surfactant-secreting cells help to keep the alveoli from collapsing. Macrophages constantly scour the alveoli for dirt and

microorganisms. A mucociliary escalator formed by mucus-secreting goblet cells and beating ciliated cells sweeps debris out of the airways.

In the gut, where more potentially damaging chemical processes occur, the absorptive epithelium is kept in good repair by constant rapid renewal. In the small intestine, stem cells in the crypts generate new absorptive, goblet, enteroendocrine, and Paneth cells, replacing most of the epithelial lining of the intestine every week. The diverse fates of the stem-cell progeny are controlled, in part at least, by the Notch signaling pathway, while the Wnt pathway is required to maintain the stem-cell population.

The liver is a more protected organ, but it too can rapidly adjust its size up or down by cell proliferation or cell death when the need arises. Differentiated hepatocytes remain able to divide throughout life, showing that a specialized class of stem cells is not always needed for tissue renewal. [↑ TOP](#)

Figure 22-18. Respiratory epithelium. The goblet cells secrete mucus, which forms a blanket over the tops of the ciliated cells. The regular, coordinated beating of the cilia sweeps the mucus up and out of the airways, carrying any debris that is stuck to it. The mechanism that coordinates the ciliary beating is a mystery, but it seems to reflect an intrinsic polarity in the epithelium. If a segment of rabbit trachea is surgically reversed, it carries on sweeping mucus, but in the wrong direction, back down toward the lung, in opposition to adjacent unreversed portions of trachea.

Histology: The Lives and Deaths of Cells in Tissues

Blood Vessels and Endothelial Cells

From the tissues that derive from the embryonic ectoderm and endoderm, we turn now to those derived from *mesoderm*. This middle layer of cells, sandwiched between ectoderm and endoderm, grows and diversifies to provide a wide range of supportive functions. It gives rise to the body's connective tissues, blood cells, and blood vessels, as well as muscle, kidney, and many other structures and cell types. We begin with blood vessels.

Almost all tissues depend on a blood supply, and the blood supply depends on endothelial cells, which form the linings of the blood vessels. Endothelial cells have a remarkable capacity to adjust their number and arrangement to suit local requirements. They create an adaptable life-support system, extending by cell migration into almost every region of the body. If it were not for endothelial cells extending and remodeling the network of blood vessels, tissue growth and repair would be impossible. Cancerous tissue is as dependent on a blood supply as is normal tissue, and this has led to a surge of interest in endothelial cell biology. It is hoped that by blocking the formation of new blood vessels through drugs that act on endothelial cells, it may be possible to block the growth of tumors (discussed in Chapter 23).

Endothelial Cells Line All Blood Vessels

The largest blood vessels are arteries and veins, which have a thick, tough wall of connective tissue and many layers of smooth muscle cells (Figure 22-22). The wall is lined by an exceedingly thin single sheet of endothelial cells, the *endothelium*, separated from the surrounding outer layers by a basal lamina. The amounts of connective tissue and smooth muscle in the vessel wall vary according to the vessel's diameter and function, but the endothelial lining is always present. In the finest branches of the vascular tree—the capillaries and sinusoids—the walls consist of nothing but endothelial cells and a basal lamina (Figure 22-23), together with a few scattered—but functionally important—*pericytes*. These are cells of the connective-tissue family, related to vascular smooth muscle cells, that wrap themselves round the small vessels (Figure 22-24).

[regulatory mechanism controlling blood...](#)

Thus, endothelial cells line the entire vascular system, from the heart to the smallest capillary, and control the passage of materials—and the transit of white blood cells—into and out of the bloodstream. A study of the embryo reveals, moreover, that arteries and veins develop from small vessels constructed solely of endothelial cells and a basal lamina: pericytes, connective tissue and smooth muscle are added later where required, under the influence of signals from the endothelial cells. The recruitment of pericytes in particular depends on PDGF-B secreted by the endothelial cells, and in mutants lacking this signal protein or its receptor, pericytes in many regions are missing. As a result, the embryonic blood vessels develop microaneurysms—microscopic pathological dilatations—that eventually rupture, as well as other abnormalities, reflecting the importance of signals exchanged in both directions between the pericytes and the endothelial cells.

Once a vessel has matured, signals from the endothelial cells to the surrounding connective tissue and smooth muscle continue to play a crucial part in regulating the vessel's function and structure. For example, the endothelial cells have mechanoreceptors that allow them to sense the shear stress due to flow of blood over their surface; by signaling this information to the surrounding cells, they enable the blood vessel to adapt its diameter and wall thickness to suit the blood flow. Endothelial cells also mediate rapid responses to neural signals for blood vessel dilation, by releasing the gas NO to make smooth muscle relax in the vessel wall, as discussed in [Chapter](#)

New Endothelial Cells Are Generated by Simple Duplication of Existing Endothelial Cells

Throughout the vascular system of the adult body, endothelial cells retain a capacity for cell division and movement. If, for example, a part of the wall of the aorta is damaged and denuded of endothelial cells, neighboring endothelial cells proliferate and migrate in to cover the exposed surface.

The proliferation of endothelial cells can be demonstrated by using ^3H -thymidine to label cells synthesizing DNA. In most adult tissues, endothelial cells turn over very slowly, with a cell lifetime ranging, for a mouse, from a couple of months (in liver and lung) to years (in brain and muscle). But endothelial cells not only repair and renew the lining of established blood vessels, they also create new blood vessels. They must do this in embryonic tissues to keep pace with growth, in normal adult tissues to support recurrent cycles of remodeling and reconstruction (as, for example, in the lining of the uterus during the menstrual cycle), and in damaged adult tissues to support repair. In such circumstances, they can be roused to proliferate with a doubling time of just a few days. There is some evidence that, where there is a call for rapid blood-vessel growth, the local population of endothelial cells may also increase by recruitment from the blood stream, which has been reported to contain small numbers of endothelial precursor cells derived from the bone

marrow. [↑ TOP](#)

New Capillaries Form by Sprouting

New vessels in the adult originate as capillaries, which sprout from existing small vessels. This process of angiogenesis occurs in response to specific signals and can be conveniently observed in naturally transparent structures, such as the cornea of the eye. Irritants applied to the cornea induce the growth of new blood vessels from the rim of tissue surrounding the cornea, which has a rich blood supply, in toward the center of the cornea, which normally has none. Thus, the cornea becomes vascularized through an invasion of endothelial cells into the tough collagen-packed corneal tissue.

Observations such as these reveal that endothelial cells that are to form a new capillary grow out from the side of an existing capillary or small venule by extending long pseudopodia, pioneering the formation of a capillary sprout that hollows out to form a tube (Figure 22-25). This process continues until the sprout encounters another capillary, with which it connects, allowing blood to circulate. Endothelial cells on the arterial and venous sides of the developing network of vessels differ in their surface properties, in the embryo at least: the plasma membranes of the arterial cells contain the transmembrane protein ephrin-B2 (see Chapter 15), while the membranes of the venous cells contain the corresponding receptor protein, Eph-B4, which is a receptor tyrosine kinase (discussed in Chapter 15). These molecules mediate a signal delivered at sites of cell-cell contact, and they are essential for the development of a properly organized network of vessels. One suggestion is that they somehow define the rules for joining one piece of growing capillary tube to another.

Experiments in culture show that endothelial cells in a medium containing suitable growth factors will spontaneously form capillary tubes, even if they are isolated from all other types of cells (Figure 22-26). The capillary tubes that develop do not contain blood, and nothing travels through them, indicating that blood flow and pressure are not required for the initiation of a new capillary network. [↑ TOP](#)

Angiogenesis Is Controlled by Factors Released by the Surrounding Tissues

Almost every cell, in almost every tissue of a vertebrate, is located within 50–100 μm of a capillary. What mechanism ensures that the system of blood vessels ramifies into every nook and cranny? How is it adjusted so perfectly to the local needs of the tissues, not only during normal development but also in all sorts of pathological circumstances? Wounding, for example, induces a burst of capillary growth in the neighborhood of the damage, to satisfy the high metabolic requirements of the repair process (Figure 22-27). Local irritants and infections also cause a proliferation of new capillaries, most of

which regress and disappear when the inflammation subsides. Less benignly, a small sample of tumor tissue implanted in the cornea, which normally lacks blood vessels, causes blood vessels to grow quickly toward the implant from the vascular margin of the cornea; the growth rate of the tumor increases abruptly as soon as the vessels reach it.

In all these cases, the invading endothelial cells respond to signals produced by the tissue that they invade. The signals are complex, but a key part is played by a protein known as **vascular endothelial growth factor (VEGF)**, a distant relative of platelet-derived growth factor (PDGF). The regulation of blood vessel growth to match the needs of the tissue depends on the control of VEGF production, through changes in the stability of its mRNA and in its rate of transcription. The latter control is relatively well understood. A shortage of oxygen, in practically any type of cell, causes an increase in the intracellular concentration of the active form of a gene regulatory protein called **hypoxia-inducible factor 1 (HIF-1)**. HIF stimulates transcription of the VEGF gene (and of other genes whose products are needed when oxygen is in short supply). The VEGF protein is secreted, diffuses through the tissue, and acts on nearby endothelial cells.

The response of the endothelial cells includes at least four components. First, the cells produce proteases to digest their way through the basal lamina of the parent capillary or venule. Second, the endothelial cells migrate toward the source of the signal. Third, the cells proliferate. Fourth, the cells form tubes and differentiate. VEGF acts on endothelial cells selectively to stimulate this entire set of effects. (Other growth factors, including some members of the fibroblast growth factor family, can also stimulate angiogenesis, but they influence other cell types besides endothelial cells.)

As the new vessels form, bringing blood to the tissue, the oxygen concentration rises, HIF-1 activity declines, VEGF production is shut off, and angiogenesis comes to a halt ([Figure 22-28](#)). As in all signaling systems, it is as important to switch the signal off correctly as to switch it on. In normal well-oxygenated tissue, the concentration of HIF-1 is kept low by continual degradation of the HIF-1 protein. This degradation depends on ubiquitylation of HIF-1—a process that requires the product of another gene, which is defective in a rare disorder called *von Hippel-Lindau (VHL) syndrome*. People with this condition are born with only one functional copy of the *VHL* gene; mutations occurring at random in the body then give rise to cells in which both gene copies are defective. These cells contain large quantities of HIF-1 regardless of oxygen availability, triggering the continual overproduction of VEGF. The result is development of *hemangioblastomas*, tumors that contain dense masses of blood vessels. The mutant cells that produce the VEGF are apparently themselves encouraged to proliferate by the over-rich nourishment provided by the excess blood vessels, creating a vicious cycle that promotes tumor growth. Loss of the *VHL* gene product also gives rise to other tumors as well as hemangioblastomas, by mechanisms that may be independent of effects on angiogenesis. [↑ TOP](#)

Summary

Endothelial cells form a single cell layer that lines all blood vessels and regulates exchanges between the bloodstream and the surrounding tissues. Signals from endothelial cells organize the growth and development of connective tissue cells that form the surrounding layers of the blood-vessel wall. New blood vessels can develop from the walls of existing small vessels by the outgrowth of endothelial cells, which have the capacity to form hollow capillary tubes even when isolated in culture. Endothelial cells of developing arteries and veins express different cell-surface proteins, which may control the way in which they link up to create a capillary bed.

A homeostatic mechanism ensures that blood vessels permeate every region of the body. Cells that are short of oxygen increase their concentration of hypoxia-inducible factor 1 (HIF-1), which stimulates the production of vascular endothelial growth factor (VEGF). VEGF acts on endothelial cells, causing them to proliferate and invade the hypoxic tissue to supply it with new blood vessels. [↑ TOP](#)

Figure 22-23. Capillaries. (A) Electron micrograph of a cross section of a small capillary in the pancreas. The wall is formed by a single endothelial cell surrounded by a basal lamina. Note the small "transcytotic" vesicles, which according to one theory provide transport of large molecules in and out of this type of capillary: materials are taken up into the vesicles by endocytosis at the luminal surface of the cell and discharged by exocytosis at the external surface, or vice versa. (B) Scanning electron micrograph of the interior of a capillary in a glomerulus of the kidney, where filtration of the blood occurs to produce urine. Here, as in the liver (see Figure 22-20), the endothelial cells are specialized to form a sieve-like structure, with fenestrae ("windows"), constructed rather like the pores in the nuclear envelope of eucaryotic cells, allowing water and most molecules to pass freely out of the bloodstream. Figure 22-26. Capillary formation *in vitro*. Endothelial cells in culture spontaneously develop internal vacuoles that appear to join up from cell to cell, giving rise to a network of capillary tubes. These photographs show successive stages in the process. The *arrow* in (A) indicates a vacuole forming initially in a single endothelial cell. The cultures are set up from small patches of two to four endothelial cells taken from short segments of capillary. These cells settle on the surface of a collagen-coated culture dish and form a small flattened colony that enlarges gradually as the cells proliferate. The colony spreads across the dish, and eventually, after about 20 days, capillary tubes begin to form in the central regions. Once tube formation has started, branches soon appear, and after 5–10 more days, an extensive network of tubes is visible, as seen in (B). The process is strongly dependent on the nature of the extracellular matrix in the environment of the cells: the formation of capillary tubes is promoted by basal lamina components, such as laminin, which the endothelial cells themselves can secrete. Figure 22-27. New capillary formation in response to wounding. Scanning electron micrographs of casts of the system of blood vessels surrounding the margin of the cornea show the reaction to wounding. The casts are made by injecting a resin into the vessels and letting the resin set; this reveals the shape of the lumen, as opposed to the shape of the cells. Sixty hours after wounding many new capillaries have begun to sprout toward the site of injury, which is just *above* the *top* of the picture. Their oriented outgrowth reflects a chemotactic response of the endothelial cells to an angiogenic factor released at the wound. (Courtesy of Peter C. Burger.)

Histology: The Lives and Deaths of Cells in Tissues

Renewal by Multipotent Stem Cells: Blood Cell Formation

Blood contains many types of cells with very different functions, ranging from the transport of oxygen to the production of antibodies. Some of these cells function entirely within the vascular system, while others use the vascular system only as a means of transport and perform their function elsewhere. All blood cells, however, have certain similarities in their life history. They all have limited life-spans and are produced throughout the life of the animal. Most remarkably, they are all generated ultimately from a common stem cell in the bone marrow. This *hemopoietic* (blood-forming) *stem cell* is thus multipotent, giving rise to all the types of terminally differentiated blood cells as well as some other types of cells, such as osteoclasts in bone, which we discuss later.

Blood cells can be classified as red or white (Figure 22-29). The **red blood cells**, or erythrocytes, remain within the blood vessels and transport O₂ and CO₂ bound to hemoglobin. The white blood cells, or **leucocytes**, combat infection and in some cases phagocytose and digest debris. Leucocytes, unlike erythrocytes, must make their way across the walls of small blood vessels and migrate into tissues to perform their tasks. In addition, the blood contains large numbers of platelets, which are not entire cells but small, detached cell fragments or "minicells" derived from the cortical cytoplasm of large cells called *megakaryocytes*. Platelets adhere specifically to the endothelial cell lining of damaged blood vessels, where they help to repair breaches and aid in the process of blood clotting.

The Three Main Categories of White Blood Cells: Granulocytes, Monocytes, and Lymphocytes

All red blood cells belong in a single class, following the same developmental trajectory as they mature, and the same is true of platelets; but there are many distinct types of white blood cells. White blood cells are traditionally grouped into three major categories—granulocytes, monocytes, and lymphocytes—on the basis of their appearance in the light microscope.

Granulocytes contain numerous lysosomes and secretory vesicles (or granules) and are subdivided into three classes according to the morphology and staining properties of these organelles (Figure 22-30). The differences in staining reflect major differences of chemistry and function. *Neutrophils* (also called *polymorphonuclear leucocytes* because of their multilobed nucleus) are the most common type of granulocyte; they phagocytose and destroy microorganisms, especially bacteria, and thus have a key role in innate immunity to bacterial infection, as discussed in Chapter 25. *Basophils* secrete histamine (and, in some species, serotonin) to help mediate inflammatory reactions; they are closely related in function to *mast cells*, which reside in connective tissues but are also generated from the hemopoietic stem cells. *Eosinophils* help to destroy parasites and modulate allergic inflammatory responses.

Once they leave the bloodstream, monocytes (see Figure 22-30D) mature into macrophages, which, together with neutrophils, are the main "professional phagocytes" in the body. As discussed in Chapter 13, both types of phagocytic cells contain specialized lysosomes that fuse with newly formed phagocytic vesicles (phagosomes), exposing phagocytosed microorganisms to a barrage of enzymatically produced, highly reactive molecules of superoxide (O_2^-) and hypochlorite ($HOCl$, the active ingredient in bleach), as well as to a concentrated mixture of lysosomal hydrolases. Macrophages, however, are much larger and longer-lived than neutrophils. They are responsible for recognizing and removing senescent, dead, and damaged cells in many tissues, and they are unique in being able to ingest large microorganisms such as protozoa.

Monocytes also give rise to *dendritic cells*, such as the *Langerhans cells* scattered in the epidermis. Like macrophages, dendritic cells are migratory cells that can ingest foreign substances and organisms; but they do not have as active an appetite for phagocytosis and are instead specialized as presenters of foreign antigens to lymphocytes to trigger an immune response. Langerhans cells, for example, ingest foreign antigens in the epidermis and carry these trophies back to present to lymphocytes in lymph nodes.

There are two main classes of lymphocytes, both involved in immune responses: *B lymphocytes* make antibodies, while *T lymphocytes* kill virus-infected cells and regulate the activities of other white blood cells. In addition, there are lymphocytelike cells called *natural killer (NK) cells*, which kill some types of tumor cells and virus-infected cells. The production of lymphocytes is a specialized topic discussed in detail in Chapter 24. Here we shall concentrate mainly on the development of the other blood cells, often referred to collectively as myeloid cells.

The various types of blood cells and their functions are summarized in Table

22-1.

The Production of Each Type of Blood Cell in the Bone Marrow Is Individually Controlled

Most white blood cells function in tissues other than the blood; blood simply transports them to where they are needed. A local infection or injury in any tissue rapidly attracts white blood cells into the affected region as part of the inflammatory response, which helps fight the infection or heal the wound.

The inflammatory response is complex and is mediated by a variety of signal molecules produced locally by mast cells, nerve endings, platelets, and white blood cells, as well as by the activation of complement (discussed in [Chapters 24 and 25](#)). Some of these signal molecules act on nearby capillaries, causing the endothelial cells to adhere less tightly to one another but making their surfaces adhesive to passing white blood cells. The white blood cells are thus caught like flies on flypaper and then can escape from the vessel by squeezing between the endothelial cells and crawling across the basal lamina with the aid of digestive enzymes. The initial binding to endothelial cells is mediated by homing receptors called *selectins*, and the stronger binding required for the white blood cells to crawl out of the blood vessel is mediated by *integrins* (see [Figure 19-30](#)). Other molecules called *chemokines* are secreted by damaged or inflamed tissue and local endothelial cells; they act as chemoattractants for specific types of white blood cells, causing these cells to become polarized and crawl toward the source of the attractant. As a result, large numbers of white blood cells enter the affected tissue ([Figure 22-31](#)).

Other signal molecules produced in the course of an inflammatory response escape into the blood and stimulate the bone marrow to produce more leucocytes and release them into the bloodstream. The bone marrow is the key target for such regulation because, with the exception of lymphocytes and some macrophages, most types of blood cells in adult mammals are generated only in the bone marrow. The regulation tends to be cell-type-specific: some bacterial infections, for example, cause a selective increase in neutrophils, while infections with some protozoa and other parasites cause a selective increase in eosinophils. (For this reason, physicians routinely use differential white blood cell counts to aid in the diagnosis of infectious and other inflammatory diseases.)

In other circumstances erythrocyte production is selectively increased—for example, in the process of acclimatization when one goes to live at high altitude, where oxygen is scarce. Thus, blood cell formation, or *hemopoiesis*, necessarily involves complex controls, by which the production of each type of blood cell is regulated individually to meet changing needs. It is a problem of great medical importance to understand how these controls operate, and much progress has been made in this area in recent years.

In intact animals, hemopoiesis is more difficult to analyze than is cell turnover in a tissue such as the epidermal layer of the skin. In the epidermis there is a simple, regular spatial organization that makes it easy to follow the process of renewal and to locate the stem cells. This is not true of the hemopoietic tissues. However, hemopoietic cells have a nomadic life-style that makes them more accessible to experimental study in other ways. Dispersed hemopoietic cells are easily obtained and can be readily transferred, without damage, from one animal to another. Moreover, the proliferation and differentiation of individual cells and their progeny can be observed and analyzed in culture, and numerous molecular markers distinguish the various stages of differentiation. Because of this, more is known about the molecules that control blood cell production than about those that control cell production in other mammalian tissues. [↑ TOP](#)

Bone Marrow Contains Hemopoietic Stem Cells

The different types of blood cells and their immediate precursors can be recognized in the bone marrow by routine staining methods ([Figure 22-32](#)). They are intermingled with one another, as well as with fat cells and other stromal cells (connective-tissue cells), which produce a delicate supporting meshwork of collagen fibers and other extracellular matrix components. In addition, the whole tissue is richly supplied with thin-walled blood vessels, called *blood sinuses*, into which the new blood cells are discharged. Megakaryocytes are also present; these, unlike other blood cells, remain in the bone marrow when mature and are one of its most striking features, being extraordinarily large (diameter up to 60 μm), with a highly polyploid nucleus. They normally lie close beside blood sinuses, and they extend processes through holes in the endothelial lining of these vessels; platelets pinch off from the processes and are swept away into the blood ([Figure 22-33](#)).

Because of the complex arrangement of the cells in bone marrow, it is difficult to identify in ordinary tissue sections any but the immediate precursors of the mature blood cells. The corresponding cells at still earlier stages of development, before any overt differentiation has begun, are confusingly similar in appearance, and although the spatial distribution of cell types has some orderly features, there is no obvious visible characteristic by which the ultimate stem cells can be recognized. To identify and characterize the stem cells, one needs a functional assay, which involves tracing the progeny of single cells. As we shall see, this can be done *in vitro* simply by examining the colonies that isolated cells produce in culture. The hemopoietic system, however, can also be manipulated so that such clones of cells can be recognized *in vivo* in the intact animal.

When an animal is exposed to a large dose of x-rays, most of the hemopoietic cells are destroyed and the animal dies within a few days as a result of its inability to manufacture new blood cells. The animal can be saved, however, by a transfusion of cells taken from the bone marrow of a healthy, immunologically compatible donor. Among these cells there are some that can

colonize the irradiated host and permanently reequip it with hemopoietic tissue (Figure 22-34). Experiments of this sort prove that the marrow contains hemopoietic stem cells. They also show how one can assay for the presence of hemopoietic stem cells and hence discover the molecular features that distinguish them from other cells.

For this purpose, cells taken from bone marrow are sorted (with the help of a fluorescence-activated cell sorter) according to the surface antigens that they display, and the different fractions are transfused back into irradiated mice. If a fraction rescues an irradiated host mouse, it must contain hemopoietic stem cells. In this way, it has been possible to show that the hemopoietic stem cells are characterized by a specific combination of cell-surface proteins, and by appropriate sorting virtually pure stem cell preparations can be obtained. The stem cells turn out to be a tiny fraction of the bone-marrow population—about 1 cell in 10,000; but this is enough. As few as five such cells injected into a host mouse with defective hemopoiesis are sufficient to reconstitute its entire hemopoietic system, generating a complete set of blood-cell types, as well as fresh stem cells. [↑ TOP](#)

A Multipotent Stem Cell Gives Rise to All Classes of Blood Cells

To see what range of cell types a single **hemopoietic stem cell** can generate, one needs a way of tracing the fate of its progeny. This can be done by marking the individual stem cell genetically, so that the progeny can be identified even after they have been released into the bloodstream. Although several methods have been used for this, a specially engineered retrovirus (a retroviral vector carrying a marker gene) serves the purpose particularly well. The marker virus, like other retroviruses, can insert its own genome into the chromosomes of the cell it infects, but the genes that would enable it to generate new infectious virus particles have been removed. The marker is therefore confined to the progeny of the cells that were originally infected, and the progeny of one such cell can be distinguished from the progeny of another because the chromosomal sites of insertion of the virus are different. To analyze hemopoietic cell lineages, bone marrow cells are first infected with the retroviral vector *in vitro* and then are transferred into a lethally irradiated recipient; DNA probes can then be used to trace the progeny of individual infected cells in the various hemopoietic and lymphoid tissues of the host. These experiments show that the individual hemopoietic stem cell is *multipotent* and can give rise to the complete range of blood cell types, both myeloid and lymphoid, as well as new stem cells like itself (Figure 22-35).

The same methods that were developed for experimentation in mice can now be used for the treatment of disease in humans. Mice, we have seen, can be irradiated to kill off their hemopoietic cells, and then rescued by a transfusion of new stem cells. In the same way, patients with leukemia, for example, can be irradiated or chemically treated to destroy their cancerous cells along with

the rest of their hemopoietic tissue, and then can be rescued by a transfusion of hemopoietic stem cells that are free of the cancer-causing mutations. These healthy stem cells can be obtained either from an immunologically matched donor, or by sorting from a sample of bone marrow previously taken from the leukemic patient himself or herself.

The same technology also opens the way, in principle, to one form of gene therapy: hemopoietic stem cells can be isolated in culture, genetically modified by DNA transfection or some other technique to introduce a desired gene, and then transfused back into a patient in whom the gene was lacking, to provide a self-renewing source of the missing genetic component. [↑ TOP](#)

Commitment Is a Stepwise Process

Hemopoietic stem cells do not jump directly from a multipotent state into a commitment to just one pathway of differentiation; instead, they go through a series of progressive restrictions. The first step is commitment to either a myeloid or a lymphoid fate. This is thought to give rise to two kinds of progenitor cells, one capable of generating large numbers of all the different types of myeloid cells, or perhaps of myeloid cells plus B lymphocytes, and the other to large numbers of all the different types of lymphoid cells, or at least T lymphocytes. Further steps give rise to progenitors committed to the production of just one cell type. The steps of commitment can be correlated with changes in the expression of specific gene regulatory proteins, needed for the production of different subsets of blood cells. These seem to act in a complicated combinatorial fashion: the *GATA-1 protein*, for example, is needed for the maturation of red blood cells, but is active also at much earlier steps in the hemopoietic pathway.

The meaning of "commitment" in molecular terms is still unclear, but it has at least two aspects: genes for the chosen mode of differentiation begin to be switched on, while access to other developmental pathways is shut off. These processes normally go hand-in-hand, but studies of mutants show that they are in principle distinct. Animals lacking the gene regulatory protein Pax5 have a block in the production of mature B lymphocytes: progenitor cells begin the process leading to B cell restriction but do not complete it. Normal progenitors that have taken the same initial step cannot be induced, no matter what their environment, to differentiate along any other pathway than that of a B lymphocyte. But the Pax5-defective cells show no such restriction: exposure to appropriate conditions can drive them to generate other blood cell types, including T lymphocytes, macrophages, and granulocytes. This is because the Pax5 protein is required not only to activate genes required for B cell development, but also to shut off genes required for development along other blood-cell pathways. [↑ TOP](#)

The Number of Specialized Blood Cells Is Amplified by Divisions of Committed Progenitor Cells

Hemopoietic progenitor cells generally become committed to a particular pathway of differentiation long before they cease proliferating and terminally differentiate. The committed progenitors go through many rounds of cell division to amplify the ultimate number of cells of the given specialized type. In this way, a single stem-cell division can lead to the production of thousands of differentiated progeny, which explains why the number of stem cells is so small a fraction of the total population of hemopoietic cells. For the same reason, a high rate of blood cell production can be maintained even though the stem-cell division rate is low. Infrequent division is a common feature of stem cells in several tissues, including epidermis and gut, as well as the hemopoietic system. The amplifying divisions of the committed progenitors reduce the number of division cycles that the stem cells themselves have to undergo in the course of a lifetime, thereby reducing the risk of replicative senescence (discussed in [Chapter 17](#)) and damaging mutations.

The stepwise nature of commitment means that the hemopoietic system can be viewed as a hierarchical family tree of cells. Multipotent stem cells give rise to *committed progenitor cells*, which are specified to give rise to only one or a few blood cell types. The committed progenitors divide rapidly, but only a limited number of times, before they terminally differentiate into cells that divide no further and die after several days or weeks. Many cells normally die at the earlier steps in the pathway as well. Studies in culture provide a way to find out how the proliferation, differentiation, and death of the hemopoietic cells are regulated. [↑ TOP](#)

Stem Cells Depend on Contact Signals From Stromal Cells

Hemopoietic cells can survive, proliferate, and differentiate in culture if, and only if, they are provided with specific signal proteins or accompanied by cells that produce these proteins. If deprived of such proteins, the cells die. For long-term maintenance, contact with appropriate supporting cells also seems to be necessary: hemopoiesis can be kept going for months or even years *in vitro* by culturing dispersed bone-marrow hemopoietic cells on top of a layer of bone-marrow stromal cells, which mimic the environment in intact bone marrow. Such cultures can generate all the types of myeloid cells, and their long-term continuation implies that stem cells, as well as differentiated progeny, are being continually produced.

There has to be some mechanism, in these cultures as well as *in vivo*, to guarantee that while some stem cell progeny become committed to differentiation, others remain as stem cells. The cell-fate choice seems to be controlled, in part at least, by specific signals generated at contacts with stromal cells. These signals seem to be needed by the hemopoietic stem cells to keep them in their uncommitted state, just as signals from contacts with the basal lamina are needed to maintain stem cells of the epidermis. In both systems, stem cells are normally confined to a particular niche, and when they lose contact with this niche, they tend to lose their stem-cell potential ([Figure](#)

22-36).

The nature of the critical signals from the stromal cells is not yet certain, although several mechanisms have been implicated, involving both secreted and cell-surface-attached factors. For example, hemopoietic precursor cells, including stem cells, in the bone marrow display the transmembrane receptor Notch1 in their plasma membrane, while marrow stromal cells express Notch ligands, and there is evidence that Notch activation helps to keep the stem cells or progenitor cells from embarking on differentiation (see [Chapter 15](#)).

Another contact interaction that is important for the maintenance of hemopoiesis came to light through the analysis of mouse mutants with a curious combination of defects: a shortage of red blood cells (anemia), of germ cells (sterility), and of pigment cells (white spotting of the skin; see [Figure 21-81](#)). As discussed in [Chapter 21](#), this syndrome results from mutations in either of two genes: one, called *c-kit*, codes for a receptor tyrosine kinase; the other, called *Steel*, codes for its ligand, stem-cell factor (SCF). The cell types affected by the mutations all derive from migratory precursors, and it seems that these precursors in each case must express the receptor (Kit) and be provided with the ligand (SCF) by their environment if they are to survive and produce progeny in normal numbers. Studies in mutant mice suggest that SCF must be membrane-bound to be effective, implying that normal hemopoiesis requires direct cell-cell contact between the hemopoietic cells that express Kit receptor protein and stromal cells that express SCF. [↑ TOP](#)

Factors That Regulate Hemopoiesis Can Be Analyzed in Culture

While stem cells depend on contact with stromal cells for long-term maintenance, their committed progeny do not, or not to the same degree. Thus, dispersed bone-marrow hemopoietic cells can be cultured in a semisolid matrix of dilute agar or methylcellulose, and factors derived from other cells can be added artificially to the medium. Because cells in the semisolid matrix cannot migrate, the progeny of each isolated precursor cell remain together as an easily distinguishable colony. A single committed neutrophil progenitor, for example, may give rise to a clone of thousands of neutrophils. Such culture systems have provided a way to assay for the factors that support hemopoiesis and hence to purify them and explore their actions. These substances are found to be glycoproteins and are usually called **colony-stimulating factors (CSFs)**. Of the growing number of CSFs that have been defined and purified, some circulate in the blood and act as hormones, while others act in the bone marrow either as secreted local mediators or, like SCF, as membrane-bound signals that act through cell-cell contact. The best understood of the CSFs that act as hormones is the glycoprotein erythropoietin, which is produced in the kidneys and regulates *erythropoiesis*, the formation of red blood cells. [↑ TOP](#)

Erythropoiesis Depends on the Hormone Erythropoietin

The erythrocyte is by far the most common type of cell in the blood (see [Table 22-1](#)). When mature, it is packed full of hemoglobin and contains practically none of the usual cell organelles. In an erythrocyte of an adult mammal, even the nucleus, endoplasmic reticulum, mitochondria, and ribosomes are absent, having been extruded from the cell in the course of its development ([Figure 22-37](#)). The erythrocyte therefore cannot grow or divide; the only possible way of making more erythrocytes is by means of stem cells. Furthermore, erythrocytes have a limited life-span—about 120 days in humans or 55 days in mice. Worn-out erythrocytes are phagocytosed and digested by macrophages in the liver and spleen, which remove more than 10^{11} senescent erythrocytes in each of us each day. Young erythrocytes actively protect themselves from this fate: they have a protein on their surface that binds to an inhibitory receptor on macrophages and thereby prevents their phagocytosis.

A lack of oxygen or a shortage of erythrocytes stimulates cells in the kidney to synthesize and secrete increased amounts of [erythropoietin](#) into the bloodstream. The erythropoietin, in turn, stimulates the production of more erythrocytes. Since a change in the rate of release of new erythrocytes into the bloodstream is observed as early as 1–2 days after an increase in erythropoietin levels in the bloodstream, the hormone must act on cells that are very close precursors of the mature erythrocytes.

The cells that respond to erythropoietin can be identified by culturing bone marrow cells in a semisolid matrix in the presence of erythropoietin. In a few days, colonies of about 60 erythrocytes appear, each founded by a single committed erythroid progenitor cell. This cell is known as an *erythrocyte colony-forming cell*, or *CFC-E*, (or colony-forming unit, *CFU-E*) and it gives rise to mature erythrocytes after about six division cycles or less. The CFC-Es do not yet contain hemoglobin, and they are derived from an earlier type of progenitor cell whose proliferation does not depend on erythropoietin. CFC-Es themselves depend on erythropoietin for their survival, as well as for proliferation: if erythropoietin is removed from the cultures, the cells rapidly undergo apoptosis.

A second CSF, called **interleukin-3 (IL-3)**, promotes the survival and proliferation of the earlier erythroid progenitor cells. In its presence, much larger erythroid colonies, each comprising up to 5000 erythrocytes, develop from cultured bone marrow cells in a process requiring a week or 10 days. These colonies derive from erythroid progenitor cells called *erythrocyte burst-forming cells*, or *BFC-Es* (or burst-forming units, *BFU-E*). A BFC-E is distinct from a multipotent stem cell in that it has a limited capacity to proliferate and gives rise to colonies that contain erythrocytes only, even under culture conditions that enable other progenitor cells to give rise to other classes of differentiated blood cells. It is distinct from a CFC-E in that it is insensitive to erythropoietin, and its progeny must go through as many as 12 divisions before they become mature erythrocytes (for which erythropoietin must be present).

Thus, the BFC-E is thought to be a progenitor cell committed to erythrocyte differentiation and an early ancestor of the CFC-E. [↑ TOP](#)

Multiple CSFs Influence the Production of Neutrophils and Macrophages

The two professional phagocytic cells, neutrophils and macrophages, develop from a common progenitor cell called a **granulocyte/macrophage (GM) progenitor cell**. Like the other granulocytes (eosinophils and basophils), neutrophils circulate in the blood for only a few hours before migrating out of capillaries into the connective tissues or other specific sites, where they survive for only a few days. They then die by apoptosis and are phagocytosed by macrophages. Macrophages, in contrast, can persist for months or perhaps even years outside the bloodstream, where they can be activated by local signals to resume proliferation.

At least seven distinct CSFs that stimulate neutrophil and macrophage colony formation in culture have been defined, and some or all of these are thought to act in different combinations to regulate the selective production of these cells *in vivo*. These CSFs are synthesized by various cell types—including endothelial cells, fibroblasts, macrophages, and lymphocytes—and their concentration in the blood typically increases rapidly in response to bacterial infection in a tissue, thereby increasing the number of phagocytic cells released from the bone marrow into the bloodstream. IL-3 is one of the least specific of the factors, acting on multipotent stem cells as well as on most classes of committed progenitor cells, including GM progenitor cells. Various other factors act more selectively on committed GM progenitor cells and their differentiated progeny ([Table 22-2](#)), although in many cases they act on certain other branches of the hemopoietic family tree as well.

All of these CSFs, like erythropoietin, are glycoproteins that act at low concentrations (about 10^{-12} M) by binding to specific cell-surface receptors, as discussed in [Chapter 15](#). A few of these receptors are transmembrane tyrosine kinases but most belong to the large cytokine receptor family, whose members are usually composed of two or more subunits, one of which is frequently shared among several receptor types ([Figure 22-38](#)). The CSFs not only operate on the precursor cells to promote the production of differentiated progeny, they also activate the specialized functions (such as phagocytosis and target-cell killing) of the terminally differentiated cells. Proteins produced artificially from the cloned genes for these factors (sometimes referred to as *recombinant proteins* because they are made using recombinant DNA technology) are strong stimulators of hemopoiesis in experimental animals. They are now widely used in human patients to stimulate the regeneration of hemopoietic tissue and to boost resistance to infection—an impressive demonstration of how basic cell biological research and animal experiments can lead to better medical treatment. [↑ TOP](#)

The Behavior of a Hemopoietic Cell Depends Partly on Chance

Up to this point we have glossed over a central question. CSFs are defined as factors that promote the production of colonies of differentiated blood cells. But precisely what effect does a CSF have on an individual hemopoietic cell? The factor might control the rate of cell division or the number of division cycles that the progenitor cell undergoes before differentiating; it might act late in the hemopoietic lineage to facilitate differentiation; it might act early to influence commitment; or it might simply increase the probability of cell survival ([Figure 22-39](#)). By monitoring the fate of isolated individual hemopoietic cells in culture, it has been possible to show that a single CSF, such as GM-CSF, can exert all these effects, although it is still not clear which are most important *in vivo*.

Studies *in vitro* indicate, moreover, that there is a large element of chance in the way a hemopoietic cell behaves. At least some of the CSFs seem to act by regulating probabilities, not by dictating directly what the cell shall do. In hemopoietic cell cultures, even if the cells have been selected to be as homogeneous a population as possible, there is a remarkable variability in the sizes and often in the characters of the colonies that develop. And if two sister cells are taken immediately after a cell division and cultured apart under identical conditions, they frequently give rise to colonies that contain different types of blood cells or the same types of blood cells in different numbers. Thus, both the programming of cell division and the process of commitment to a particular path of differentiation seem to involve random events at the level of the individual cell, even though the behavior of the multicellular system as a whole is regulated in a reliable way. [↑ TOP](#)

Regulation of Cell Survival Is as Important as Regulation of Cell Proliferation

While such observations show that CSFs are not strictly required to instruct the hemopoietic cells how to differentiate or how many times to divide, CSFs are required to keep the cells alive: the default behavior of the cells in the absence of CSFs is death by apoptosis (discussed in [Chapter 17](#)). In principle, the CSFs could regulate the numbers of the various types of blood cells entirely through selective control of cell survival in this way, and there is increasing evidence that the control of cell survival plays a central part in regulating the numbers of blood cells, just as it does for hepatocytes and many other cell types, as we have already seen. The amount of apoptosis in the vertebrate hemopoietic system is enormous: billions of neutrophils die in this way each day in an adult human, for example. Indeed, the vast majority of neutrophils produced in the bone marrow die there without ever functioning. This futile cycle of production and destruction presumably serves to maintain a reserve supply of cells that can be promptly mobilized to fight infection whenever it flares up, or phagocytosed and digested for recycling when all is quiet. Compared with the

life of the organism, the lives of cells are cheap.

Too little cell death can be as dangerous to the health of a multicellular organism as too much proliferation. In the hemopoietic system, mutations that inhibit cell death by causing excessive production of the intracellular apoptosis inhibitor Bcl-2 promote the development of cancer in B lymphocytes. Indeed, the capacity for unlimited self-renewal is a dangerous property for any cell to possess, and many cases of leukemia arise through mutations that confer this capacity on committed hemopoietic precursor cells that would normally be fated to differentiate and die after a limited number of division cycles. [↑ TOP](#)

Summary

The many types of blood cells, including erythrocytes, lymphocytes, granulocytes, and macrophages, all derive from a common multipotent stem cell. In the adult, hemopoietic stem cells are found mainly in bone marrow, and they depend on contact-mediated signals from the marrow stromal (connective-tissue) cells to maintain their stem-cell character. The stem cells normally divide infrequently to produce more stem cells (self-renewal) and various committed progenitor cells (transit amplifying cells), each able to give rise to only one or a few types of blood cells. The committed progenitor cells divide extensively under the influence of various protein signal molecules (colony-stimulating factors, or CSFs) and then terminally differentiate into mature blood cells, which usually die after several days or weeks.

Studies of hemopoiesis have been greatly aided by in vitro assays in which stem cells or committed progenitor cells form clonal colonies when cultured in a semisolid matrix. The progeny of stem cells seem to make their choices between alternative developmental pathways in a partly random manner. Cell death by apoptosis, controlled by the availability of CSFs, also plays a central part in regulating the numbers of mature differentiated blood cells. [↑ TOP](#)

Figure 22-31. The migration of white blood cells out of the bloodstream during an inflammatory response. The response is initiated by a variety of signal molecules produced locally by cells (mainly in the connective tissue) or by complement activation. Some of these mediators act on capillary endothelial cells, causing them to loosen their attachments to their neighbors so that the capillaries become more permeable. Endothelial cells are also stimulated to express selectins, cell-surface molecules that recognize specific carbohydrates that are present on the surface of leucocytes in the blood and cause them to stick to the endothelium. Other mediators called chemokines are secreted by the inflamed tissues and local endothelial cells and act as

Figure 22-35. A tentative scheme of hemopoiesis. The multipotent stem cell normally divides infrequently to generate either more multipotent stem cells, which are self-renewing, or committed progenitor cells, which are limited in the number of times that they can divide before differentiating to form mature blood cells. As they go through their divisions, the progenitors become progressively more specialized in the range of cell types that they can give rise to, as indicated by the branching of the cell-lineage diagram in the region enclosed in the *gray box*. Many of the details of this part of the lineage diagram are still controversial, however. In adult mammals, all of the cells shown develop mainly in the bone marrow—except for T lymphocytes, which develop in the thymus, and macrophages and osteoclasts, which develop from blood monocytes. Some dendritic cells may also derive from monocytes. Mast cells (not shown) are thought to develop from circulating basophils.

Histology: The Lives and Deaths of Cells in Tissues

Genesis, Modulation, and Regeneration of Skeletal Muscle

The term "muscle" covers a multitude of cell types, all specialized for contraction but in other respects dissimilar. As noted in [Chapter 16](#), a contractile system involving actin and myosin is a basic feature of animal cells in general, but muscle cells have developed this apparatus to a high degree. Mammals possess four main categories of cells specialized for contraction: skeletal muscle cells, heart (cardiac) muscle cells, smooth muscle cells, and myoepithelial cells ([Figure 22-40](#)). These differ in function, structure, and development. Although all of them generate contractile forces by means of organized filament systems based on actin and myosin, the actin and myosin molecules employed are somewhat different in amino acid sequence, are differently arranged in the cell, and are associated with different sets of proteins to control contraction.

Skeletal muscle cells are responsible for practically all movements that are under voluntary control. These cells can be very large (2–3 cm long and 100 μm in diameter in an adult human) and are often referred to as *muscle fibers* because of their highly elongated shape. Each one is a syncytium, containing many nuclei within a common cytoplasm. The other types of muscle cells are more conventional, generally having only a single nucleus. **Heart muscle cells** resemble skeletal muscle fibers in that their actin and myosin filaments are aligned in very orderly arrays to form a series of contractile units called *sarcomeres*, so that the cells have a striated (striped) appearance. Smooth muscle cells are so named because they do not appear striated. The functions of smooth muscle vary greatly, from propelling food along the digestive tract to erecting hairs in response to cold or fear. Myoepithelial cells also have no striations, but unlike all other muscle cells they lie in epithelia and are derived from the ectoderm. They form the dilator muscle of the eye's iris and serve to expel saliva, sweat, and milk from the corresponding glands, as discussed earlier (see [Figure 22-8](#)). The four main categories of muscle cells can be further divided into distinctive subtypes, each with its own characteristic features.

 [Figure 22-40. The four classes of muscle...](#)

 [Figure 22-41. Myoblast fusion in culture.](#)

 [Figure 22-42. Fast and slow muscle fibers.](#)

 [Figure 22-43. Regulation of muscle size by...](#)

 [Figure 22-44. A satellite cell on a...](#)

The mechanisms of muscle contraction are discussed in [Chapter 16](#). Here we consider how muscle tissue is generated and maintained. We focus on the skeletal muscle fiber, which has a curious mode of development, a striking ability to modulate its differentiated character, and an unusual strategy for repair.

New Skeletal Muscle Fibers Form by the Fusion of Myoblasts

The previous chapter described how certain cells, originating from the somites of a vertebrate embryo at a very early stage, become determined as [myoblasts](#), the precursors of skeletal muscle fibers. As discussed in [Chapter 7](#), the commitment to be a myoblast depends on gene regulatory proteins of at least two families—the *MyoD* family of basic helix-loop-helix proteins, and the *MEF2* family of MADS box proteins. These act in combination to give the myoblast a memory of its committed state, and, eventually, to regulate the expression of other genes that give the mature muscle cell its specialized character (see [Figure 7-72](#)). After a period of proliferation, the myoblasts undergo a dramatic switch of phenotype that depends on the coordinated activation of a whole battery of muscle-specific genes, a process known as myoblast differentiation. As they differentiate, they fuse with one another to form multinucleate skeletal muscle fibers ([Figure 22-41](#)). Fusion involves specific cell-cell adhesion molecules that mediate recognition between newly differentiating myoblasts and fibers. Once differentiation has occurred, the cells do not divide and the nuclei never again replicate their DNA.

Myoblasts that have been kept proliferating in culture for as long as two years still retain the ability to differentiate and can fuse to form muscle cells in response to a suitable change in culture conditions. Appropriate signal proteins such as fibroblast or hepatocyte growth factor (FGF or HGF) in the culture medium can maintain myoblasts in the proliferative, undifferentiated state: if these soluble factors are removed, the cells rapidly stop dividing, differentiate, and fuse. The system of controls is complex, however, and attachment to the extracellular matrix is also important for myoblast differentiation. Moreover, the process of differentiation is cooperative: differentiating myoblasts secrete factors that apparently encourage other myoblasts to differentiate. In the intact animal, the myoblasts and muscle fibers are held in the meshes of a connective-tissue framework formed by fibroblasts. This framework guides muscle development and controls the arrangement and orientation of the muscle cells. [↑ TOP](#)

Muscle Cells Can Vary Their Properties by Changing the Protein Isoforms They Contain

variant copies of the genes encoding many of the characteristic proteins of the skeletal muscle cell, and the RNA transcripts of many of these genes can be spliced in several ways. As a result, a wealth of protein variants (isoforms) can be produced for the components of the contractile apparatus. As the muscle fiber matures, different isoforms are produced, adapted to the changing demands for speed, strength, and endurance in the fetus, the newborn, and the adult. Within a single adult muscle, several distinct types of skeletal muscle fibers, each with different sets of protein isoforms and different functional properties, can be found side by side ([Figure 22-42](#)). Slow muscle fibers (for sustained contraction) and fast muscle fibers (for rapid twitch) are innervated by slow and fast motor neurons, respectively, and the innervation can regulate muscle-fiber gene expression and size through the different patterns of electrical stimulation that these neurons deliver. [↑ TOP](#)

Skeletal Muscle Fibers Secrete Myostatin to Limit Their own Growth

A muscle can grow in three ways: its fibers can increase in number, in length, or in girth. Because skeletal muscle fibers are unable to divide, more of them can be made only by the fusion of myoblasts, and the adult number of multinucleated skeletal muscle fibers is in fact attained early—before birth, in humans. Once formed, a skeletal muscle fiber generally survives for the entire lifetime of the animal. However, individual muscle nuclei can be added or lost. Thus, the enormous postnatal increase in muscle bulk is achieved by cell enlargement. Growth in length depends on recruitment of more myoblasts into the existing multinucleated fibers, which increases the number of nuclei in each cell. Growth in girth, such as occurs in the muscles of weightlifters, involves both myoblast recruitment and an increase in the size and numbers of the contractile myofibrils that each muscle fiber nucleus supports.

What, then, are the mechanisms that control muscle cell numbers and muscle cell size? One part of the answer lies in an extracellular signal protein called *myostatin*. Mice with a loss-of-function mutation in the myostatin gene have enormous muscles—two to three times larger than normal ([Figure 22-43](#)). Both the numbers and the size of the muscle cells seem to be increased. Mutations in the same gene turn out to be present in so-called "double-muscling" breeds of cattle (see [Figure 17-51](#)): in selecting for big muscles, cattle breeders have unwittingly selected for myostatin deficiency. Myostatin belongs to the TGF β superfamily of signal proteins, and it is normally made and secreted by skeletal muscle cells. Its function, evidently, is to provide negative feedback to limit muscle growth. Small amounts of the protein can be detected in the circulation of adult humans, and it has been reported that the amount is raised in AIDS patients who show muscle wasting. Thus, myostatin may act as a negative regulator of muscle growth in adult life as well as during development. The growth of some other organs is similarly controlled by a negative-feedback action of a factor that they themselves produce. We shall encounter another example in a later section. [↑ TOP](#)

Some Myoblasts Persist as Quiescent Stem Cells in the Adult

Even though humans do not normally generate new skeletal muscle fibers in adult life, the capacity for doing so is not completely lost. Cells capable of serving as myoblasts are retained as small, flattened, and inactive cells lying in close contact with the mature muscle cell and contained within its sheath of basal lamina ([Figure 22-44](#)). If the muscle is damaged, these *satellite cells* are activated to proliferate, and their progeny can fuse to repair the damaged muscle. Satellite cells are thus the stem cells of adult skeletal muscle, normally held in reserve in a quiescent state but available when needed as a self-renewing source of terminally differentiated cells. Athletes who specialize in muscular strength often damage their muscle fibers and are thought to depend on this mechanism for muscle repair, resulting in regenerated fibers that are often highly branched.

The process of muscle repair by means of satellite cells is, nevertheless, limited in what it can achieve. In one form of *muscular dystrophy*, for example, differentiated skeletal muscle cells are damaged because of a genetic defect in the cytoskeletal protein dystrophin. As a result, satellite cells proliferate to repair the damaged muscle fibers. This regenerative response is, however, unable to keep pace with the damage, and the muscle cells are eventually replaced by connective tissue, blocking any further possibility of regeneration. A similar loss of capacity for repair seems to contribute to the weakening of muscle in the elderly.

In muscular dystrophy, where the satellite cells are constantly called upon to proliferate, their capacity to divide may become exhausted as a result of progressive shortening of their telomeres in the course of each cell cycle (discussed in [Chapter 17](#)). Stem cells of other tissues, such as blood, are limited in the same way: they normally divide only at a slow rate, and mutations or exceptional circumstances that cause them to divide more rapidly can lead to premature exhaustion of the stem-cell supply. [↑ TOP](#)

Summary

Skeletal muscle fibers are one of the four main categories of vertebrate cells specialized for contraction, and they are responsible for all voluntary movement. Each skeletal muscle fiber is a syncytium and develops by the fusion of many myoblasts. Myoblasts proliferate extensively, but once they have fused, they can no longer divide. Fusion generally follows the onset of myoblast differentiation, in which many genes encoding muscle-specific proteins are switched on coordinately. Some myoblasts persist in a quiescent state as satellite cells in adult muscle; when a muscle is damaged, these cells are reactivated to proliferate and to fuse to replace the muscle cells that have been lost. Muscle bulk is regulated homeostatically by a negative-feedback mechanism, in which existing muscle secretes myostatin, which inhibits

further muscle growth. [↑ TOP](#)

Histology: The Lives and Deaths of Cells in Tissues

Fibroblasts and Their Transformations: The Connective-Tissue Cell Family

Many of the differentiated cells in the adult body can be grouped into families whose members are closely related by origin and by character. An important example is the family of connective-tissue cells, whose members are not only related but also unusually interconvertible. The family includes *fibroblasts*, *cartilage cells*, and *bone cells*, all of which are specialized for the secretion of collagenous extracellular matrix and are jointly responsible for the architectural framework of the body. The connective-tissue family also includes *fat cells* and *smooth muscle cells*. These cell types and the interconversions that are thought to occur between them are illustrated in Figure 22-45. Connective-tissue cells play a central part in the support and repair of almost every tissue and organ, and the adaptability of their differentiated character is an important feature of the responses to many types of damage.

Fibroblasts Change Their Character in Response to Chemical Signals

Fibroblasts seem to be the least specialized cells in the connective-tissue family. They are dispersed in connective tissue throughout the body, where they secrete a nonrigid extracellular matrix that is rich in type I and/or type III collagen, as discussed in Chapter 19. When a tissue is injured, the fibroblasts nearby proliferate, migrate into the wound, and produce large amounts of collagenous matrix, which helps to isolate and repair the damaged tissue. Their ability to thrive in the face of injury, together with their solitary lifestyle, may explain why fibroblasts are the easiest of cells to grow in culture—a feature that has made them a favorite subject for cell biological studies (Figure 22-46).

As indicated in Figure 22-45, fibroblasts also seem to be the most versatile of connective-tissue cells, displaying a remarkable capacity to differentiate into other members of the family. There are uncertainties about their interconversions, however. Strong evidence indicates that fibroblasts in different parts of the body are intrinsically different, and there may be

differences between them even in a single region. "Mature" fibroblasts with a lesser capacity for transformation may, for example, exist side by side with "immature" fibroblasts (often called mesenchymal cells) that can develop into a variety of mature cell types.

The stromal cells of bone marrow, mentioned earlier, provide a good example of connective-tissue versatility. These cells, which can be regarded as a kind of fibroblast, can be isolated from the bone marrow and propagated in culture. Large clones of progeny can be generated in this way from single ancestral stromal cells. According to the signal proteins that are added to the culture medium, the members of such a clone can either continue proliferating to produce more cells of the same type, or can differentiate as fat cells, cartilage cells, or bone cells. Because of their self-renewing, multipotent character, they are referred to as *mesenchymal stem cells*.

Fibroblasts from the skin are different. Placed in the same culture conditions, they do not show the same plasticity. Yet they, too, can be induced to change their character. At a healing wound, for example, they change their actin gene expression and take on some of the contractile properties of smooth muscle cells, thereby helping to pull the wound margins together; such cells are called *myofibroblasts*. More dramatically, if a preparation of bone matrix, made by grinding bone into a fine powder and dissolving away the hard mineral component, is implanted in the dermal layer of the skin, some of the cells there (probably fibroblasts) become transformed into cartilage cells, and a little later, others transform into bone cells, thereby creating a small lump of bone. These experiments suggest that components in the extracellular matrix can dramatically influence the differentiation of connective-tissue cells.

We shall see that similar cell transformations are important in the natural repair of broken bones. In fact, bone matrix contains high concentrations of several signal proteins that can affect the behavior of connective-tissue cells. These include members of the TGF β superfamily, including BMPs and TGF β itself. These factors are powerful regulators of growth, differentiation, and matrix synthesis by connective-tissue cells, exerting a variety of actions depending on the target cell type and the combination of other factors and matrix components that are present. When injected into a living animal, they can induce the formation of cartilage, bone, or fibrous matrix, according to the site and circumstances of injection. TGF β is especially important in wound healing, where it stimulates conversion of fibroblasts into myofibroblasts and promotes formation of the collagen-rich scar tissue that gives a healed wound its strength. [↑ TOP](#)

The Extracellular Matrix May Influence Connective-Tissue Cell Differentiation by Affecting Cell Shape and Attachment

The extracellular matrix may influence the differentiated state of connective-tissue cells through physical as well as chemical effects. This has been shown

in studies on cultured cartilage cells, or chondrocytes. Under appropriate culture conditions, these cells proliferate and maintain their differentiated character, continuing for many cell generations to synthesize large quantities of highly distinctive cartilage matrix, with which they surround themselves. If, however, the cells are kept at relatively low density and remain as a monolayer on the culture dish, a transformation occurs. They lose their characteristic rounded shape, flatten down on the substratum, and stop making cartilage matrix: they stop producing type II collagen, which is characteristic of cartilage, and start producing type I collagen, which is characteristic of fibroblasts. By the end of a month in culture, almost all the cartilage cells have switched their collagen gene expression and taken on the appearance of fibroblasts. The biochemical change must occur abruptly, since very few cells are observed to make both types of collagen simultaneously.

Several lines of evidence suggest that the biochemical change is induced at least in part by the change in cell shape and attachment. Cartilage cells that have made the transition to a fibroblastlike character, for example, can be gently detached from the culture dish and transferred to a dish of agarose. By forming a gel around them, the agarose holds the cells suspended without any attachment to a substratum, forcing them to adopt a rounded shape. In these circumstances, the cells promptly revert to the character of chondrocytes and start making type II collagen again. Cell shape and anchorage may control gene expression through intracellular signals generated at focal contacts by integrins acting as matrix receptors, as discussed in Chapter 19.

For most types of cells, and especially for a connective-tissue cell, the opportunities for anchorage and attachment depend on the surrounding matrix, which is usually made by the cell itself. Thus, a cell can create an environment that then acts back on the cell to reinforce its differentiated state. Furthermore, the extracellular matrix that a cell secretes forms part of the environment for its neighbors as well as for the cell itself, and thus tends to make neighboring cells differentiate in the same way (see Figure 19-61). A group of chondrocytes forming a nodule of cartilage, for example, either in the developing body or in a culture dish, can be seen to enlarge by the conversion of neighboring fibroblasts into chondrocytes.  [TOP](#)

Fat Cells Can Develop From Fibroblasts

Fat cells, or adipocytes, also derive from fibroblastlike cells, both during normal mammalian development and in various pathological circumstances. In muscular dystrophy, for example, where the muscle cells die, they are gradually replaced by fatty connective tissue, probably by conversion of local fibroblasts. Fat cell differentiation (whether normal or pathological) begins with the expression of two families of gene regulatory proteins: the *C/EBP* (CCAAT/enhancer binding protein) family and the *PPAR* (peroxisome proliferator-activated receptor) family, especially *PPAR γ* . Like the *MyoD* and *MEF2* families in skeletal muscle development, the *C/EBP* and *PPAR γ*

proteins drive and maintain one another's expression, through various cross-regulatory and autoregulatory control loops. They work together to control the expression of the other genes characteristic of adipocytes.

The production of enzymes for import of fatty acids and glucose and for fat synthesis leads to an accumulation of fat droplets, consisting mainly of triacylglycerol (see [Figure 2-77](#)). These then coalesce and enlarge until the cell is hugely distended (up to 120 μm in diameter), with only a thin rim of cytoplasm around the mass of lipid ([Figures 22-47](#) and [22-48](#)). Lipases are also made in the fat cell, giving it the capacity to reverse the process of lipid accumulation, by breaking down the triacylglycerols into fatty acids that can be secreted for consumption by other cells. The fat cell can change its volume by a factor of a thousand as it accumulates and releases lipid. [↑ TOP](#)

Leptin Secreted by Fat Cells Provides Negative Feedback to Inhibit Eating

For almost all animals under natural circumstances, food supplies are variable and unpredictable. Fat cells have the vital role of storing reserves of nourishment in times of plenty and releasing them in times of dearth. It is thus essential to the function of adipose tissue that its quantity should be adjustable throughout life, according to the supply of nutrients. For our ancestors, this was a blessing; in the well-fed half of the modern world, it has become also a curse. In the United States, for example, it is estimated that more than 30% of the population suffer from obesity, defined as a body mass index (weight/height²) more than 30 kg/m², equivalent to about 30% above ideal weight.

It is not easy to determine to what extent the changes in the quantity of adipose tissue depend on changes in the numbers of fat cells, as opposed to changes in fat-cell size. Changes in cell size are probably the main factor in normal nonobese adults, but in severe obesity, at least, the number of fat cells also increases. The factors that drive the recruitment of new fat cells are not well understood, although they are thought to include growth hormone and IGF-1 (insulinlike growth factor-1). It is clear, however, that the increase or decrease of fat cell size is regulated directly by levels of circulating nutrients and by hormones, such as insulin, that reflect nutrient levels. The surplus of food intake over energy expenditure thus directly governs the accumulation of adipose tissue.

But how are food intake and energy expenditure themselves regulated? A human adult eats about a million kilocalories per year, equivalent to about 200 kg of pure fat. Clearly, if we are not to get hopelessly fat or hopelessly thin over the course of a lifetime, there must be control mechanisms to adjust our eating and energy expenditure over the long term according to the quantity of our fat reserves. The key signal is a protein hormone called **leptin**, which circulates in the bloodstream. Mutant mice that lack leptin or the appropriate leptin receptor are extremely fat ([Figure 22-49](#)). Mutations in the same genes

sometimes occur in humans, although very rarely. The consequences are similar: constant hunger, overeating, and crippling obesity.

Leptin is normally made by fat cells; the bigger they are, the more they make. Leptin acts on many tissues, and in particular in the brain, on cells in those regions of the hypothalamus that regulate eating behavior. The effect in the brain is to lessen hunger and discourage eating, which results in a decreased amount of fat tissue. Thus, leptin, like myostatin released from muscle cells, provides a negative-feedback mechanism to regulate the growth of the tissue that secretes it.

In most obese people, leptin levels in the blood stream are persistently high. Although leptin receptors are present and functional, the effect of leptin on food intake is overwhelmed by other influences, which are poorly understood. [↑ TOP](#)

Bone Is Continually Remodeled by the Cells Within It

Bone is a very dense, specialized form of connective tissue, as different as could be from adipose tissue, even though closely related in origin. Like reinforced concrete, bone matrix is predominantly a mixture of tough fibers (type I collagen fibrils), which resist pulling forces, and solid particles (calcium phosphate as hydroxyapatite crystals), which resist compression. The volume occupied by the collagen is nearly equal to that occupied by the calcium phosphate. The collagen fibrils in adult bone are arranged in regular plywoodlike layers, with the fibrils in each layer lying parallel to one another but at right angles to the fibrils in the layers on either side.

For all its rigidity, bone is by no means a permanent and immutable tissue. Running through the hard extracellular matrix are channels and cavities occupied by living cells, which account for about 15% of the weight of compact bone. These cells are engaged in an unceasing process of remodeling: one class of cells (*osteoclasts*, related to macrophages) demolishes old bone matrix while another (*osteoblasts*, related to fibroblasts) deposits new bone matrix. This mechanism provides for continuous turnover and replacement of the matrix in the interior of the bone.

Unlike soft tissues, which can grow by internal expansion, bone can grow only by apposition—that is, by the laying down of additional matrix and cells on the free surfaces of existing bone. During development, this process must occur in coordination with the growth of other tissues, in such a way that the pattern of the body can be scaled up without its proportions being radically disturbed. For most of the skeleton, and in particular for the long bones of the limbs and trunk, the coordinated growth is achieved by a complex strategy. A set of minute "scale models" of these bones are first formed out of cartilage. Each scale model then grows, and as new cartilage is formed, the older cartilage is replaced by bone. Cartilage growth and erosion and bone deposition are so ingeniously coordinated during development that the adult

bone, though it may be half a meter long, is almost the same shape as the initial cartilaginous model, which was no more than a few millimeters long.

Defective growth of cartilage during the development of long bones, as a result of a dominant mutation in the gene that codes for an FGF receptor (FGFR3), is responsible for the commonest form of dwarfism, known as *achondroplasia* (Figure 22-50). Conversely, osteoblasts are lacking in individuals with mutations that disrupt production of a gene regulatory protein (called CBFA1) specifically required for osteoblast differentiation: mice homozygous for this genetic defect are born with a skeleton consisting solely of cartilage and die soon after birth as a result. [↑ TOP](#)

Osteoblasts Secrete Bone Matrix, While Osteoclasts Erode It

Cartilage is a simple tissue, consisting of cells of a single type—chondrocytes—embedded in a more or less uniform matrix. The cartilage matrix is deformable, and the tissue grows by expanding as the chondrocytes divide and secrete more matrix (Figure 22-51). Bone is more complex. The bone matrix is secreted by osteoblasts that lie at the surface of the existing matrix and deposit fresh layers of bone onto it. Some of the osteoblasts remain free at the surface, while others gradually become embedded in their own secretion. This freshly formed material (consisting chiefly of type I collagen) is called *osteoid*. It is rapidly converted into hard bone matrix by the deposition of calcium phosphate crystals in it. Once imprisoned in hard matrix, the original bone-forming cell, now called an **osteocyte**, has no opportunity to divide, although it continues to secrete further matrix in small quantities around itself. The osteocyte, like the chondrocyte, occupies a small cavity, or *lacuna*, in the matrix, but unlike the chondrocyte it is not isolated from its fellows. Tiny channels, or *canaliculi*, radiate from each lacuna and contain cell processes from the resident osteocyte, enabling it to form gap junctions with adjacent osteocytes (Figure 22-52). Although the networks of osteocytes do not themselves secrete or erode substantial quantities of matrix, they probably play a part in controlling the activities of the cells that do.

While bone matrix is deposited by osteoblasts, it is eroded by osteoclasts (Figure 22-53). These large multinucleated cells originate, like macrophages, from hemopoietic stem cells in the bone marrow. The precursor cells are released as monocytes into the bloodstream and collect at sites of bone resorption, where they fuse to form the multinucleated osteoclasts, which cling to surfaces of the bone matrix and eat it away. Osteoclasts are capable of tunneling deep into the substance of compact bone, forming cavities that are then invaded by other cells. A blood capillary grows down the center of such a tunnel, and the walls of the tunnel become lined with a layer of osteoblasts (Figure 22-54). To produce the plywoodlike structure of compact bone, these osteoblasts lay down concentric layers of new matrix, which gradually fill the cavity, leaving only a narrow canal surrounding the new blood vessel. Many of

the osteoblasts become trapped in the bone matrix and survive as concentric rings of osteocytes. At the same time as some tunnels are filling up with bone, others are being bored by osteoclasts, cutting through older concentric systems. The consequences of this perpetual remodeling are beautifully displayed in the layered patterns of matrix observed in compact bone ([Figure 22-55](#)).

Through remodelling, bones are endowed with a remarkable ability to adjust their structure in response to long-term variations in the load imposed on them. This adaptive behavior implies that the deposition and erosion of the matrix are somehow controlled by local mechanical stresses, but the mechanisms involved are not understood. The bone cells secrete signal proteins that become trapped in the matrix, and it is likely that these are released when the matrix is degraded or suitably stressed. The released proteins, especially members of the BMP subfamily of TGF β proteins, may help to guide the remodelling process.

Remodelling carries a risk: defects in its control can lead to *osteoporosis*, where there is excessive erosion of the bone matrix and weakening of the bone, or to the opposite condition, *osteopetrosis*, where the bone becomes excessively thick and dense. [↑ TOP](#)

During Development, Cartilage Is Eroded by Osteoclasts to Make Way for Bone

The replacement of cartilage by bone in the course of development is also thought to depend on the activities of osteoclasts. As the cartilage matures, its cells in certain regions become greatly enlarged at the expense of the surrounding matrix, and the matrix itself becomes mineralized, like bone, by the deposition of calcium phosphate crystals. The swollen chondrocytes die, leaving large empty cavities. Osteoclasts and blood vessels invade the cavities and erode the residual cartilage matrix, while osteoblasts following in their wake begin to deposit bone matrix. The only surviving remnant of cartilage in the adult long bone is a thin layer that forms a smooth covering on the bone surfaces at joints, where one bone articulates with another ([Figure 22-56](#)).

Some cells capable of forming new cartilage persist, however, in the connective tissue that surrounds a bone. If the bone is broken, the cells in the neighborhood of the fracture repair it by a sort of recapitulation of the original embryonic process: cartilage is first laid down to bridge the gap and is then replaced by bone.

The capacity for self-repair, so strikingly illustrated by the tissues of the skeleton, is a property of living structures that has no parallel among present-day man-made objects. [↑ TOP](#)

Summary

The family of connective-tissue cells includes fibroblasts, cartilage cells, bone cells, fat cells, and smooth muscle cells. Some classes of fibroblasts seem to be able to transform into any of the other members of the family. These transformations of connective-tissue cell type are regulated by the composition of the surrounding extracellular matrix, by cell shape, and by hormones and growth factors. While the chief function of most members of the family is to secrete extracellular matrix, fat cells serve as storage sites for fat. The quantity of fat tissue is regulated in part by negative feedback: fat cells release a hormone, leptin, which acts in the brain to reduce appetite, which leads to a decrease in fat tissue.

Cartilage and bone both consist of cells embedded in a solid matrix. The matrix of cartilage is deformable so that the tissue can grow by swelling, whereas bone is rigid and can grow only by apposition. Bone undergoes perpetual remodeling through which it can adapt to the load it bears; the remodelling depends on the combined action of osteoclasts, which erode matrix, and osteoblasts, which secrete it. Some osteoblasts become trapped in the matrix as osteocytes and play a part in regulating the turnover of bone matrix. Most long bones develop from miniature cartilage "models," which, as they grow, serve as templates for the deposition of bone by the combined action of osteoblasts and osteoclasts. Similarly, in the repair of a bone fracture in the adult, the gap is first bridged by cartilage, which is later replaced by bone. [↑ TOP](#)

Figure 22-50. Achondroplasia. This type of dwarfism has a frequency of one in 10,000–100,000 births; in more than 99% of cases it is caused by a mutation at an identical site in the genome, corresponding to amino-acid 380 in FGF-receptor-3 (a glycine in the transmembrane domain). The mutation is dominant, and almost all cases are due to new, independently occurring mutations, implying an extraordinarily high mutation rate at this particular site in the genome. The defect in FGF signaling causes dwarfism by interfering with the growth of cartilage in developing long bones. (From Velasquez's painting of Sebastian de Morra. © Museo del Prado, Madrid.)

Figure 22-54. The remodeling of compact bone. Osteoclasts acting together in a small group excavate a tunnel through the old bone, advancing at a rate of about 50 μm per day. Osteoblasts enter the tunnel behind them, line its walls, and begin to form new bone, depositing layers of matrix at a rate of 1–2 μm per day. At the same time, a capillary sprouts down the center of the tunnel. The tunnel eventually becomes filled with concentric layers of new bone, with only a narrow central canal remaining. Each such canal, besides providing a route of access for osteoclasts and osteoblasts, contains one or more blood vessels that transport the nutrients the bone cells require for survival. Typically, about 5–10% of the bone in a healthy adult mammal is replaced in this way each year. (After Z.F.G. Jaworski, B. Duck, and G. Sekaly, *J. Anat.* 133:397–405, 1981.)

Figure 22-55. A transverse section through a compact outer portion of a long bone. The micrograph shows the outlines of tunnels formed by osteoclasts and then filled in by osteoblasts during successive rounds of bone remodeling. The section has been prepared by grinding. The hard matrix has been preserved, but not the cells. Lacunae and canaliculi that were occupied by osteocytes are clearly visible, however. The alternating bright and dark concentric rings correspond to an alternating orientation of the collagen fibers in the successive layers of bone matrix laid down by the osteoblasts that lined the wall of the canal during life. (This pattern is revealed here by viewing the specimen between partly crossed polarizing filters.) Note how older systems of concentric layers of bone have been partly cut through and replaced by newer systems.

Figure 22-56. The development of a long bone. Long bones, such as the femur or the humerus, develop from a miniature cartilage model. Uncalcified cartilage is shown in *light green*, calcified cartilage in *dark green*, bone in *black*, and blood vessels in *red*. The cartilage is not converted to bone but is gradually replaced by it through the action of osteoclasts and osteoblasts, which invade the cartilage in association with blood vessels. Osteoclasts erode cartilage and bone matrix, while osteoblasts secrete bone matrix. The process of ossification begins in the embryo and is not completed until the end of puberty. The resulting bone consists of a thick-walled hollow cylinder of compact bone enclosing a large central cavity occupied by the bone marrow. Note that not all bones develop in this way. The membrane bones of the skull, for example, are formed directly as bony plates, not from a prior cartilage model. (Adapted from D.W. Fawcett, *A Textbook of Histology*, 12th edn. New York: Chapman and Hall, 1994.)

Histology: The Lives and Deaths of Cells in Tissues

Stem-Cell Engineering

When cells are removed from the body and maintained in culture, they generally maintain their original character. Keratinocytes continue to behave as keratinocytes, chondrocytes as chondrocytes, liver cells as liver cells, and so on. Each type of specialized cell has a memory of its developmental history and seems fixed in its specialized fate, although some limited transformations can occur, just as in the intact tissues we discussed earlier. Stem cells in culture, as in tissues, may continue to divide, or they may differentiate into one or more cell types, but the cell types they can generate are restricted. Each type of stem cell serves for the renewal of one particular type of tissue. For some tissues, such as the brain, it was long thought that regeneration is impossible in adult life because no stem cells remain. There seemed to be little hope, therefore, of replacing lost nerve cells in the mammalian brain through the genesis of new ones, or of regenerating any other cell type whose normal progenitors are no longer present.

Recent discoveries have overturned this gloomy judgement and have led to a more optimistic perception of what stem cells can do and how we may be able to use them. The change has come from several findings that demonstrate exceptional forms of stem-cell versatility that could scarcely have been suspected from knowledge of the normal life histories of cells in tissues. In this last section of the chapter, we examine these phenomena and consider the new opportunities they create to improve on nature's own mechanisms of damage repair.

ES Cells Can Be Used to Make Any Part of the Body

As described in Chapter 21, it is possible through cell culture to derive from early mouse embryos an extraordinary class of stem cells called embryonic stem cells, or **ES cells**. ES cells can be kept proliferating indefinitely in culture and yet retain an unrestricted developmental potential. If they are put back into an early embryonic environment, they can give rise to all the tissues and cell types in the body, including germ cells. They integrate perfectly into whatever site they may come to occupy, adopting the character and behavior that normal cells would show at that site. One can think of development in terms of a series

[Figure 22-57.](#)

[Production of differentiated cells from...](#)

[Figure 22-58. The](#)

[continuing production of neurons...](#)

of choices presented to cells as they follow a road that leads from the fertilized egg to terminal differentiation. After their long sojourn in culture, the ES cell and its progeny can evidently still read the signs at each branch in the highway and respond as normal embryonic cells would.

Cells with properties similar to those of mouse ES cells can now be derived from early human embryos and from human fetal ovaries and testes, creating a potentially inexhaustible supply of cells that might be used for the replacement and repair of mature human tissues that are damaged. Whether or not one has ethical objections to such use of human embryos, it is worth considering the possibilities that are opened up. Setting aside the dream of growing entire organs from ES cells by a recapitulation of embryonic development, experiments in mice suggest that it will be possible in the near future to use ES cells to replace the skeletal muscle fibers that degenerate in victims of muscular dystrophy, the nerve cells that die in patients with Parkinson's disease, the insulin-secreting cells that are lacking in type I diabetics, the heart muscle cells that die in a heart attack, and so on.

Mouse ES cells can be induced to differentiate into a variety of cell types in culture ([Figure 22-57](#)). When treated with a carefully chosen combination of signal proteins, for example, the ES cells differentiate into astrocytes and oligodendrocytes, the two main types of glial cells in the central nervous system. If the treated ES cells are injected into a mouse brain, they can serve as progenitors of these cell types. If the host mouse is deficient in myelin-forming oligodendrocytes, for example, the grafted cells can correct the deficiency and form myelin sheaths around axons that lack them. [↑ TOP](#)

Epidermal Stem Cell Populations Can Be Expanded in Culture for Tissue Repair

It is a long way still from this sort of success in mice to routine treatments for human diseases. One of the main difficulties lies in immune rejection. If ES-derived cells of one genotype are grafted into an individual of another, the grafted cells are likely to be rejected by the immune system as foreign. Methods of dealing with this problem have been developed for the transplantation of organs such as kidneys and hearts. Immunological problems—and some ethical problems—can, however, be avoided altogether if the right kinds of stem cells can be obtained from the patient's own body.

A simple example is the use of epidermal stem cells for repair of the skin after extensive burns. By culturing cells from undamaged regions of the skin of the burned patient, it is possible to obtain epidermal stem cells quite rapidly in large numbers. These can then be used to repopulate the damaged body surface. For good results after a third-degree burn, however, it is essential to provide first of all an urgent replacement for the lost dermis. For this, dermis taken from a human cadaver can be used, or an artificial dermis substitute. This is still an area of active experimentation. In one technique, an artificial

Search

All

matrix of collagen mixed with a glycosaminoglycan is formed into a sheet, with a thin membrane of silicone rubber covering its external surface as a barrier to water loss, and this skin substitute (called Integra) is laid on the burned body surface after the damaged tissue has been cleaned away. Fibroblasts and blood capillaries from the patient's surviving deep tissues migrate into the artificial matrix and gradually replace it with new connective tissue. Meanwhile, the epidermal cells are cultivated until there are enough to form a thin sheet of adequate extent. Two or more weeks after the original operation, the silicone rubber membrane is carefully removed and replaced with this cultured epidermis, so as to reconstruct a complete skin. [↑ TOP](#)

Neural Stem Cells Can Repopulate the Central Nervous System

While the epidermis is one of the simplest and most easily regenerated tissues, the central nervous system (the CNS) is the most complex and seems the most difficult to reconstruct in adult life. The adult mammalian brain and spinal cord have very little capacity for self-repair. Stem cells capable of generating new neurons are hard to find in adult mammals—so hard to find, indeed, that until recently they were thought to be absent.

It is now known, however, that CNS neural stem cells capable of giving rise to both neurons and glial cells do persist in the adult mammalian brain. Moreover, in certain parts of the brain they continually produce new neurons to replace those that die ([Figure 22-58](#)). Neuronal turnover occurs on a more dramatic scale in certain songbirds, where large numbers of neurons die each year and are replaced by newborn neurons as part of the process by which a new song is learned in each breeding season.

In experiments with rodents, adult neural stem cells have been harvested from the brain, grown in culture, and then implanted back into the brain of a host animal, where they produce differentiated progeny. Remarkably, it seems that the grafted cells adjust their behavior to match their new location. Stem cells from the hippocampus, for example, implanted in the olfactory-bulb-precursor pathway (see [Figure 22-58](#)) give rise to neurons that become correctly incorporated into the olfactory bulb, and vice versa. These findings hold out the hope that, in spite of the extraordinary complexity of nerve cell types and neuronal connections, it may be possible to use neural stem cells to repair at least some types of damage and disease in the central nervous system. [↑ TOP](#)

The Stem Cells of Adult Tissues May Be More Versatile Than They Seem

Do cells with unexpected stem-cell capabilities lurk in other parts of the body also? If embryonic stem cells can be caused to differentiate along any pathway we please, is it possible to induce other kinds of stem cells, taken from adult

tissues, to produce cell types other than their standard range of progeny?

There is now strong evidence that the answer is yes. It has been reported, for example, that neural stem cells, derived from adult brain, can give rise to hemopoietic cells when injected onto a mouse whose own stock of hemopoietic cells has been depleted by x-irradiation. These neural stem cells have also been found to give rise to skeletal muscle cells when injected directly into muscle tissue.

As another important example, cells from adult bone marrow, when injected into x-irradiated recipients, can not only supply the host with fresh hemopoietic cells, but can also give rise to various other cell types, including pneumocytes in the lung and hepatocytes in the liver. Genesis of liver cells (and some other equally surprising cell types) from bone-marrow cells has been demonstrated both in mice and in humans who have received bone-marrow transplants for the treatment of leukemia. Well-differentiated hepatocytes displaying genetic markers proving that they come from the donor are found in the liver of the host. Experiments in mice have shown that the hepatocytes in such cases derive specifically from the hemopoietic stem cells in the bone marrow.

When the host liver is itself defective or damaged, so as to encourage its repopulation by grafted cells, hepatocytes derived from donor hemopoietic cells can be found in plenty. It is not yet clear, however, how readily the conversion of cell fate takes place. It may be that any given hemopoietic stem cell has only a small probability of switching to an alien fate, even when placed in the appropriate alien environment. As yet, we have only a very hazy idea of which transitions are permitted or what factors provoke or inhibit them.

Stem cells taken directly from adult tissues promise to be useful in many ways for tissue repair, but other strategies may have even greater potential. In principle, at least, it should even be possible to use adult tissues to derive "personalized" ES cells—that is, ES cells with the same genome as the adult patient whose body is in need of repair. The cloning of Dolly the sheep and of other mammals has indicated a way to do this. The nucleus of an egg cell can be artificially replaced by a nucleus derived from an adult cell, and the hybrid cell can then go on to develop into an entire individual whose nuclear genome is identical to that of the adult donor (see [Figure 7-2](#)). While most of us would not wish to make human beings in this way, it should be possible to obtain ES cells from the immediate descendants of the hybrid cell, by techniques like those used to derive ES cells from early mouse embryos.

Serious ethical issues to need be resolved and enormous technical problems overcome before such an approach can become a reality. Perhaps other, better ways will be found to restore adult cells to an embryonic state of versatility. But by one route or another, it seems that cell biology is beginning to open up new opportunities for improving on Nature's mechanisms of tissue repair, remarkable as those mechanisms are. [↑ TOP](#)

Summary

In the normal adult body, different classes of stem cells are responsible for the renewal of different types of tissue. Some tissues, however, seem incapable of repair by the genesis of new cells because no competent stem cells are present. Recent discoveries have opened up new possibilities for manipulating stem-cell behavior artificially so as to repair tissues that previously seemed unrepairable. Epidermal stem cells taken from undamaged skin of a badly burned patient can be rapidly grown in large numbers in culture and grafted back to reconstruct an epidermis to cover the burns. Neural stem cells persist in a few regions of the adult mammalian brain, and when grafted into a developing or damaged brain can generate new neurons and glia appropriate to the site of grafting.

Embryonic stem cells (ES cells) are able to differentiate into any cell type in the body, and they can be induced to differentiate into many cell types in culture. Stem cells of some adult tissues, such as bone marrow, when placed in a suitable environment, seem able to generate a much wider range of differentiated cell types than they produce normally. These findings of stem-cell biology offer the hope of remedy for many serious diseases. [↑ TOP](#)

Figure 22-57. Production of differentiated cells from mouse ES cells in culture. ES cells derived from an early mouse embryo can be cultured indefinitely as a monolayer, or allowed to form aggregates called embryoid bodies, in which the cells begin to specialize. Cells from embryoid bodies, cultured in media with different factors added, can then be driven to differentiate in various ways. (Based on E. Fuchs and J.A. Segre, *Cell* 100:143–155, 2000.)

Figure 22-58. The continuing production of neurons in an adult mouse brain. The brain is viewed from above, in a cut-away section, to show the region lining the ventricles of the forebrain where neural stem cells are found. These cells continually produce progeny that migrate to the olfactory bulb, where they differentiate as neurons. The constant turnover of neurons in the olfactory bulb is presumably linked in some way to the turnover of the olfactory receptor neurons that project to it from the olfactory epithelium, as discussed earlier. There is also a continuing turnover of neurons in the adult hippocampus, a region specially concerned with learning and memory, where plasticity of adult function seems to be associated with turnover of a specific subset of neurons (Adapted from B. Barres, *Cell* 97:667–670, 1999.)

23. Cancer

Cancer cells break the most basic rules of behavior by which multicellular organisms are built and maintained, and they exploit every kind of opportunity to do so. In studying the transgressions, we discover what the normal rules are and how they are enforced. Thus, in the context of cell biology, cancer has a unique importance, and the emphasis given to cancer research has profoundly benefited a much wider area of medical knowledge than that of cancer alone.

We have already discussed many offshoots of cancer research in the preceding chapters. Indeed, the effort to combat cancer has driven many fundamental discoveries in cell biology. Many proteins involved in DNA repair ([Chapter 5](#)), cell signaling ([Chapter 15](#)), the cell cycle and programmed cell death ([Chapter 17](#)), and tissue architecture ([Chapter 19](#)) were discovered because abnormalities in their function can lead to the uncontrolled proliferation, genetic mayhem, and other antisocial behavior characteristic of cancer cells.

In this chapter, we first consider more closely what cancer is and examine the natural history of the disease from a cellular standpoint. Next we review the molecular changes that make a cell cancerous. Finally, we discuss how our enhanced understanding of the molecular basis of cancer is leading to improved methods for the prevention and treatment of the disease. [↑ TOP](#)

Molecular Biology of the Cell → V. Cells in Their Social Context → 23. Cancer

Cancer as a Microevolutionary Process

The body of an animal operates as a society or ecosystem whose individual members are cells, reproducing by cell division and organized into collaborative assemblies or tissues. In our earlier discussion of the maintenance of tissues ([Chapter 22](#)), our interests were similar to those of the ecologist: cell births, deaths, habitats, territorial limitations, and the maintenance of population sizes. The one ecological topic conspicuously absent was that of natural selection: we said nothing of competition or mutation among somatic cells. The reason is that a healthy body is in this respect a very peculiar society, where self-sacrifice—as opposed to survival of the fittest—is the rule. Ultimately, all somatic cell lineages are committed to die: they leave no progeny and instead dedicate their existence to support of the germ cells, which alone have a chance of survival. There is no mystery in this, for the body is a clone, and the genome of the somatic cells is the same as that of the germ cells. By their self-sacrifice for the sake of the germ cells, the somatic cells help to propagate copies of their own genes.

Thus, unlike free-living cells such as bacteria, which compete to survive, the cells of a multicellular organism are committed to collaboration. To coordinate their behavior, the cells send, receive, and interpret an elaborate set of signals that serve as social controls, telling each of them how to act (see [Chapter 15](#)). As a result, each cell behaves in socially responsible manner, resting, dividing, differentiating, or dying as needed for the good of the organism. Molecular disturbances that upset this harmony mean trouble for a multicellular society. In a human body with more than 10^{14} cells, billions of cells experience mutations every day, potentially disrupting the social controls. Most dangerously, a mutation may give one cell a selective advantage, allowing it to divide more vigorously than its neighbors and to become a founder of a growing mutant clone. A mutation that gives rise to such selfish behavior by individual members of the cooperative can jeopardize the future of the whole enterprise. Repeated rounds of mutation, competition, and natural selection operating within the population of somatic cells cause matters to go from bad to worse. These are the basic ingredients of cancer: it is a disease in which individual mutant clones of cells begin by prospering at the expense of their neighbors, but in the end destroy the whole cellular society.

In this section we discuss the development of cancer as a microevolutionary process. This process occurs on a time scale of months or years in a population of cells in the body, but it depends on the same principles of mutation and natural selection that govern the long-term evolution of all living organisms.

Cancer Cells Reproduce Without Restraint and Colonize Foreign Tissues

Cancer cells are defined by two heritable properties: they and their progeny (1) reproduce in defiance of the normal restraints on cell division and (2) invade and colonize territories normally reserved for other cells. It is the combination of these actions that makes cancers peculiarly dangerous. An isolated abnormal cell that does not proliferate more than its normal neighbors does no significant damage, no matter what other disagreeable properties it may have; but if its proliferation is out of control, it will give rise to a tumor, or *neoplasm*—a relentlessly growing mass of abnormal cells. As long as the neoplastic cells remain clustered together in a single mass, however, the tumor is said to be benign. At this stage, a complete cure can usually be achieved by removing the mass surgically. A tumor is considered a cancer only if it is malignant, that is, only if its cells have acquired the ability to invade surrounding tissue. Invasiveness usually implies an ability to break loose, enter the bloodstream or lymphatic vessels, and form secondary tumors, called **metastases**, at other sites in the body (Figure 23-1). The more widely a cancer spreads, the harder it becomes to eradicate.

Cancers are classified according to the tissue and cell type from which they arise. Cancers arising from epithelial cells are termed carcinomas; those arising from connective tissue or muscle cells are termed sarcomas. Cancers that do not fit in either of these two broad categories include the various leukemias, derived from hemopoietic cells, and cancers derived from cells of the nervous system. Figure 23-2 shows the types of cancers that are common in the United States, together with their incidence and resulting death rate. Each of the broad categories has many subdivisions according to the specific cell type, the location in the body, and the structure of the tumor; many of the names used are fixed by tradition and have no modern rational basis.

In parallel with the set of names for malignant tumors, there is a related set of names for benign tumors: an *adenoma*, for example, is a benign epithelial tumor with a glandular organization, the corresponding type of malignant tumor being an *adenocarcinoma* (Figure 23-3); similarly a *chondroma* and a *chondrosarcoma* are, respectively, benign and malignant tumors of cartilage. About 90% of human cancers are carcinomas, perhaps because most of the cell proliferation in the body occurs in epithelia, or because epithelial tissues are most frequently exposed to the various forms of physical and chemical damage that favor the development of cancer.

Each cancer has characteristics that reflect its origin. Thus, for example, the cells of an epidermal *basal-cell carcinoma*, derived from a keratinocyte stem cell in the skin, will generally continue to synthesize cytokeratin intermediate filaments, whereas the cells of a *melanoma*, derived from a pigment cell in the skin, will often (but not always) continue to make pigment granules. Cancers originating from different cell types are, in general, very different diseases. The basal-cell carcinoma, for example, is only locally invasive and rarely forms metastases, whereas the melanoma, if not removed promptly, is much more malignant and rapidly gives rise to many metastases (behavior that recalls the migratory tendencies of the normal pigment-cell precursors during development, discussed in [Chapter 21](#)). The basal-cell carcinoma is usually easy to remove by surgery, leading to complete cure; but the malignant melanoma, once it has metastasized widely, is often impossible to eliminate and consequently fatal. [↑ TOP](#)

Most Cancers Derive From a Single Abnormal Cell

Even when a cancer has metastasized, its origins can usually be traced to a single **primary tumor**, arising in an identified organ and presumed to be derived by cell division from a single cell that has undergone some heritable change that enables it to outgrow its neighbors. By the time it is first detected, however, a typical tumor already contains about a billion cells or more ([Figure 23-4](#)), often including many normal cells—fibroblasts, for example, in the supporting connective tissue that is associated with a carcinoma. What evidence do we have that the cancer cells are indeed a clone descended from a single abnormal cell?

One clear demonstration of clonal evolution comes from analysis of the chromosomes in tumor cells. Chromosomal aberrations and rearrangements are present in the cells of most common cancers. In almost all patients with *chronic myelogenous leukemia*, for example, leukemic white blood cells can be distinguished from normal cells by a specific chromosomal abnormality: the so-called Philadelphia chromosome, created by a translocation between the long arms of chromosomes 9 and 22, as shown in [Figure 23-5](#). When the DNA at the site of translocation is cloned and sequenced, it is found that the site of breakage and rejoining of the translocated fragments is identical in all the leukemic cells in any given patient, but differs slightly (by a few hundred or thousand base pairs) from one patient to another, as expected if each case of the leukemia arises from a unique accident occurring in a single cell. We will see later how this Philadelphia translocation leads to leukemia by inappropriately activating a specific gene.

Many other lines of evidence, from a variety of cancers, point to the same conclusion: most cancers originate from a single aberrant cell ([Figure 23-6](#)). [↑ TOP](#)

Cancers Result From Somatic Mutation

If a single abnormal cell is to give rise to a tumor, it must pass on its abnormality to its progeny: the aberration has to be heritable. A first problem in understanding a cancer is to discover whether the heritable aberration is due to a genetic change—that is, an alteration in the cell's DNA sequence—or to an *epigenetic* change—that is, a change in the pattern of gene expression without a change in the DNA sequence. Heritable epigenetic changes, reflecting cell memory, occur during normal development, as manifest in the stability of the differentiated state and in such phenomena as X-chromosome inactivation and imprinting (discussed in [Chapter 7](#)). Such epigenetic changes have also been found to play a part in the development of some cancers.

There are, however, good reasons to think that the vast majority of cancers are initiated by genetic changes. First, cells of a variety of cancers can be shown to have a shared abnormality in their DNA sequence that distinguishes them from the normal cells surrounding the tumor, as in the example of chronic myelogenous leukemia that we have just described.

Second, many of the agents known to give rise to cancer also cause genetic changes. Thus *carcinogenesis* (the generation of cancer) appears to be linked with *mutagenesis* (the production of a change in the DNA sequence). This correlation is clear for three classes of agents: **chemical carcinogens** (which typically cause simple local changes in the nucleotide sequence), ionizing radiations such as x-rays (which typically cause chromosome breaks and translocations), and viruses (which introduce foreign DNA into the cell). We will discuss each of these agents in detail later, in the section on the preventable causes of cancer.

Finally, the conclusion that somatic mutations underlie cancer is supported by studies of people who inherit a strong susceptibility to the disease. In a significant proportion of cases, the propensity to cancer can be traced to a genetic defect of some sort in the DNA repair mechanisms of these individuals, which allows them to accumulate mutations at an elevated rate. People with the disease *xeroderma pigmentosum*, for example, have defects in the cellular system that repairs DNA damage induced by UV light, and they experience a hugely increased incidence of skin cancers. [↑ TOP](#)

A Single Mutation Is Not Enough to Cause Cancer

An estimated 10^{16} cell divisions take place in a normal human body in the course of a lifetime; in a mouse, with its smaller number of cells and its shorter life span, the number is about 10^{12} . Even in an environment that is free of mutagens, mutations will occur spontaneously at an estimated rate of about 10^{-6} mutations per gene per cell division—a value set by fundamental limitations on the accuracy of DNA replication and repair. Thus, in a lifetime, every single gene is likely to have undergone mutation on about 10^{10} separate occasions in any individual human being, or about 10^6 occasions in a mouse.

Among the resulting mutant cells one might expect that there would be many that have disturbances in genes that regulate cell division and that consequently disobey the normal restrictions on cell proliferation. From this point of view, the problem of cancer seems to be not why it occurs but why it occurs so infrequently.

Clearly, if a single mutation were enough to convert a typical healthy cell into a cancer cell that proliferates without restraint, we would not be viable organisms. Many types of evidence indicate that the genesis of a cancer typically requires that several independent, rare accidents occur in the lineage of one cell. One such indication comes from epidemiological studies of the incidence of cancer as a function of age ([Figure 23-7](#)). If a single mutation were responsible, occurring with a fixed probability per year, the chance of developing cancer in any given year should be independent of age. In fact, for most types of cancer the incidence rises steeply with age—as would be expected if cancer is caused by a slow accumulation of numerous random mutations in a single line of cells. (An additional reason for the increased incidence of cancer in old age is discussed later, when we come to the topic of replicative cell senescence.)

Now that many of the specific mutations responsible for the development of cancer have been identified, we can test directly for their presence in a particular case of the disease. Such tests have revealed that an individual malignant cell generally harbors multiple mutations. Animal models also confirm that a single one of these genetic alterations is insufficient to cause cancer: when genetically engineered in a mouse, a single such mutation typically produces mild abnormalities in tissue growth, followed occasionally by the formation of randomly scattered benign tumors; but the vast majority of cells in the mutant animal remain non-cancerous.

The concept that the development of a cancer requires mutations in many genes—perhaps ten or more—fits with a large body of information, dating back over many years, concerning the phenomenon of [tumor progression](#), whereby an initial mild disorder of cell behavior evolves gradually into a full-blown cancer. As we explain next, these observations of how tumors develop also provide insight into the nature of the changes that must occur for a normal cell to become a cancer cell. [↑ TOP](#)

Cancers Develop in Slow Stages From Mildly Aberrant Cells

For those cancers that have a discernible external cause, the disease does not usually become apparent until long after exposure to the causal agent: the incidence of lung cancer does not begin to rise steeply until after 10 or 20 years of heavy smoking; the incidence of leukemias in Hiroshima and Nagasaki did not show a marked rise until about 5 years after the explosion of the atomic bombs; industrial workers exposed for a limited period to chemical carcinogens do not usually develop the cancers characteristic of their

occupation until 10, 20, or even more years after the exposure ([Figure 23-8](#)). During this long incubation period, the prospective cancer cells undergo a succession of changes. The same applies to cancers where the initial genetic lesion has no such obvious external cause.

Chronic myelogenous leukemia, mentioned earlier, provides a clear and simple example. This disease begins as a disorder characterized by a nonlethal overproduction of white blood cells and continues as such for several years before changing into a much more rapidly progressing illness that usually ends in death within a few months. In the chronic early phase, the leukemic cells in the body are distinguished mainly by their possession of the chromosomal translocation mentioned previously (although there may well be other genetic changes that are not seen so easily). In the subsequent acute phase of the illness, the hemopoietic system is overrun by cells that show not only this chromosomal abnormality but also several others. It appears as though members of the initial mutant clone have undergone further mutations that make them proliferate more rapidly (or divide more times before they die or terminally differentiate), so that they come to outnumber both the normal hemopoietic cells and their relatives that have only the primary chromosomal translocation (the Philadelphia chromosome).

Carcinomas and other solid tumors are thought to evolve in a similar way. Although most such cancers in humans are not diagnosed until a relatively late stage, in a few cases it is possible to observe the early steps in the development of the disease. We shall discuss one example—*colorectal cancer*—toward the end of this chapter. Another example is provided by cancers of the *uterine cervix* (the neck of the womb). These cancers are thought to derive from the epithelium near the opening of the cervix.

This epithelium undergoes physiological changes in structure at different times in a woman's reproductive life. In a cervical region liable to give rise to cancer, under the conditions in which the disease originates, the cells are initially organized as a stratified (multilayered) squamous epithelium ([Figure 23-9A,E](#)), similar in structure to the epidermis of the skin or the lining of the inside of the mouth (see p. 1274). In such stratified epithelia, proliferation normally occurs only in the basal layer, generating cells that then move out toward the surface; these cells differentiate as they move, forming flattened, keratin-rich, nondividing cells that are sloughed off as they reach the surface. When specimens of cervical epithelium from different women are examined, however, it is not unusual to find patches in which this organization is disturbed in a way that suggests the beginnings of a cancerous transformation. Pathologists describe these changes as *intraepithelial neoplasia*, and classify them as low-grade (mild) or high-grade (moderate to severe).

In the low-grade lesions, dividing cells are no longer confined to the basal layer but occupy the lower third of the epithelium; although differentiation proceeds in the upper epithelial layers, it is slightly disordered ([Figure 23-9B,E](#)). Left alone, most of these mild lesions will spontaneously regress, but a

small number (about 10%) may progress to become high-grade lesions. In these more seriously abnormal patches, most or all of the epithelial layers are occupied by undifferentiated dividing cells, which are usually highly variable in cell and nuclear size and shape. Abnormal mitotic figures are frequently seen and the karyotype is usually abnormal, but the abnormal cells are still confined to the epithelial side of the basal lamina ([Figure 23-9C,G](#)). The presence of such lesions can be detected by scraping off a sample of cells from the surface of the cervix and viewing it under the microscope (the "Pap smear" technique—[Figure 23-10](#)). At this stage, it is still easy to achieve a complete cure by destroying or removing the abnormal tissue surgically.

Without treatment, the abnormal tissue may simply persist and progress no further or may even regress spontaneously; but in at least 30–40% of cases, progression will occur, giving rise, over a period of several years, to a frank invasive carcinoma ([Figure 23-9D,H](#))—a malignant lesion where cells cross or destroy the basal lamina, invade the underlying tissue, and metastasize via the lymphatic vessels. Surgical cure becomes progressively more difficult as the invasive growth spreads. [↑ TOP](#)

Tumor Progression Involves Successive Rounds of Mutation and Natural Selection

As we have seen, cancers in general seem to arise by a process in which an initial population of slightly abnormal cells, descendants of a single mutant ancestor, evolves from bad to worse through successive cycles of mutation and natural selection. At each stage, one cell acquires an additional mutation that gives it a selective advantage over its neighbors, making it better able to thrive in its environment—an environment that, inside a tumor, may be harsh, with low levels of oxygen, scarce nutrients, and the natural barriers to growth presented by the surrounding normal tissues. The offspring of this well-adapted cell will continue to divide, eventually taking over the tumor and becoming the dominant clone in the developing lesion ([Figure 23-11](#)). Thus, tumors grow in fits and starts, as additional advantageous mutations arise and the cells bearing them flourish. Their evolution involves a large element of chance and usually takes many years; most of us die of other ailments before cancer has had time to develop.

Why are so many mutations needed? One reason is that cellular processes are controlled in complex and interconnected ways; cells employ redundant regulatory mechanisms to help them maintain tight and precise control over their behavior. Thus, many different regulatory systems have to be disrupted before a cell can throw off its normal restraints and behave defiantly as a malignant cancer cell. In addition, tumor cells may meet new barriers to further expansion at each stage of the evolutionary process. For example, oxygen and nutrients do not become limiting until a tumor is one or two millimeters in diameter, at which point the cells in the tumor interior may not have adequate access to such necessary resources. Each new barrier, whether

physical or physiological, must be overcome by the acquisition of additional mutations.

In general, the rate of evolution in any population would be expected to depend on four main parameters: (1) the *mutation rate*, that is, the probability per gene per unit time that any given member of the population will undergo genetic change; (2) the *number of individuals* in the population; (3) the *rate of reproduction*, that is, the average number of generations of progeny produced per unit time; and (4) the *selective advantage* enjoyed by successful mutant individuals, that is, the ratio of the number of surviving fertile progeny they produce per unit time to the number of surviving fertile progeny produced by nonmutant individuals. These are the critical factors for the evolution of cancer cells in a multicellular organism, just as they are for the evolution of organisms on the surface of the Earth.

Clearly the rate of progression toward cancer depends on many things beside the changing genotype of the individual cancer cell. Equally, it is plain that there are a number of quite disparate genetic properties that might help a cancer cell to be evolutionarily successful. In later sections, we shall examine the molecular changes that confer these properties. But first it is helpful to consider in general terms what the key properties actually are: what special capabilities are common to the majority of cancer cells and responsible for their bad behavior? [↑ TOP](#)

Most Human Cancer Cells Are Genetically Unstable

The great majority of human cancers show signs of a dramatically enhanced mutation rate: the cells are said to be **genetically unstable**. This instability can take various forms. Some cancer cells are defective in the ability to repair local DNA damage or to correct replication errors that affect individual nucleotides. These cells tend to accumulate more point mutations and small, localized DNA sequence changes than do normal cells. Other cancer cells have trouble maintaining the integrity of their chromosomes and thus display gross abnormalities in their karyotype ([Figure 23-12](#)). From an evolutionary perspective this is not a surprise: one might expect that genetic instability would promote the formation of cancer, as it increases the probability that cells will experience a mutation that will lead toward malignancy. In fact, it seems that some degree of genetic instability may be essential for the development of cancer; at the very least it appears to make a powerful contribution to cancer progression.

Different tumors—even from the same tissues—can show different kinds of genetic instability, caused by mutations in one or another of a very specific set of genes whose products are needed to protect the genome from alteration. As mentioned earlier, people who inherit mutations in these genes are found to have a raised incidence of cancer. Although such cancer-prone conditions are relatively rare, they include examples of mutations in practically every type of gene known to be required for genetic stability, confirming that loss of this

stability can have a causative role in cancer no matter how it occurs.

Most often, the destabilizing mutations are not inherited, but arise *de novo* as a tumor develops, helping the cancer cell to accumulate mutations much more rapidly than its neighbors do. It is important, however, to note that genetic instability does not, in itself, give a cell a selective advantage. On the contrary, genetic instability actually damages a cell's fitness, as most random mutations are harmful. Thus, a genetically unstable cell will not be favored by selection, unless it has additional properties or manages to accrue additional mutations that confer some competitive advantage. It seems that some "optimum" level of genetic instability exists for the development of cancer, making a cell mutable enough to evolve dangerously, but not so mutable that it dies ([Figure 23-13](#)). [↑ TOP](#)

Cancerous Growth Often Depends on Defective Control of Cell Death or Cell Differentiation

Just as an increased mutation rate can raise the probability of cancer progression, so can any circumstance that increases the number of cells available for mutating. The bigger the clone of mutant cells resulting from an early mutation, the greater the chance that an additional mutation will allow the cancer to progress, until its growth is completely out of control and malignant. Thus, at every stage in the development of cancer, mutations that help cells to increase in number are critical.

How can a mutation have this effect? The most obvious way is to increase the rate of cell division. Indeed, mutations that tend to make cells blind to the normal restraints on cell division are a common feature of cancer, as we shall discuss in detail later. It has become increasingly clear, however, that such mutations are not the only—or necessarily the most important—mechanism for increasing cell number. In normal adult tissues, especially those at risk of cancer, cells may proliferate continually; but their numbers remain steady because cell production is balanced by cell loss. Programmed cell death by apoptosis very often has an essential role in this balance, as we saw in [Chapters 17](#) and [22](#). If too many cells are generated, the rate of apoptosis increases to dispose of the surplus. One of the most important properties of cancer cells, therefore, is that they fail to commit suicide when a normal cell would honorably do so.

Mutations can also increase the size of a clone of mutant cells by altering their ability to differentiate, as illustrated by the situation in the uterine cervix, discussed earlier. Like the epidermis of the skin and many other epithelia, the epithelium of the uterine cervix normally renews itself continually by shedding terminally differentiated cells from its outer surface and generating replacements from stem cells in the basal layer. On average, each normal stem cell division generates one daughter stem cell and one cell that is condemned to terminal differentiation and a cessation of cell division. If the stem cell

divides more rapidly, terminally differentiated cells will be produced and shed more rapidly, but a balance of genesis and destruction will still be maintained. Thus, for an abnormal stem cell to generate a steadily growing clone of mutant progeny, the basic rules must be upset: either more than 50% of the daughter cells must remain as stem cells or the process of differentiation must be deranged so that daughter cells that embark on this route somehow retain an ability to carry on dividing indefinitely and avoid dying or being discarded at the end of the production line ([Figure 23-14](#)).

Presumably, the development of such properties underlies the progression from low-grade intraepithelial neoplasia of the uterine cervix to high-grade intraepithelial neoplasia and malignant cancer (see [Figure 23-9](#)). Similar considerations apply to the development of cancer in other tissues that rely on stem cells, such as the skin, the lining of the gut, and the hemopoietic system. Several forms of leukemia, for example, seem to arise from a disruption of the normal program of differentiation, such that a committed progenitor of a particular type of blood cell continues to divide indefinitely, instead of differentiating terminally in the normal way and dying after a strictly limited number of division cycles (as discussed in [Chapter 22](#)).

In conclusion, changes that block the normal maturation of cells toward a nondividing, terminally differentiated state or prevent normal programmed cell death play an essential part in many cancers. [↑ TOP](#)

Many Cancer Cells Escape a Built-in Limit to Cell Proliferation

Many normal cells cease to divide when they mature into terminally differentiated, specialized cells. Differentiation is not, however, the only condition that can arrest cell proliferation. Cells also cease to divide when they are stressed or when they detect damage to their DNA. Further, most normal human cells, when removed from a tissue and tested in culture for their ability to proliferate, appear to show a set limit on the number of times they can divide. Once cells progress through a certain number of population doublings—25 to 50 for human fibroblasts, for example—they simply stop proliferating, a process termed [replicative cell senescence](#) (discussed in [Chapter 17](#)). It is possible that, as a person ages, some cells may reach this limit to their proliferation— particularly in tissues requiring constant renewal, such as the epidermis or the lining of the gut. If a cell in such circumstances is to persist in dividing so as to generate a cancer, it must escape the restraints of replicative senescence. In fact, cancer cells, when tested in culture, often behave as "immortalized": they continue dividing indefinitely, unlike their normal counterparts.

While these facts are well established, it is not yet clear precisely how they relate to the cancer disease process. Despite the findings in culture, there is remarkably little solid information about the importance of replicative

senescence in normal tissues of intact human beings. According to one view, replicative senescence is a useful mechanism to protect us against cancer—an added barrier that cancer cells have to break through. According to another school of thought, cells in most tissues never actually reach replicative senescence in the course of a human lifetime, and the "immortality" of cancer cells is merely a side-effect of selection for some other property they need to have. Some recent studies, discussed later in the chapter, suggest a third view, radically different from both of the other two. The proposal is that many cells in normal tissues undergo replicative cell senescence and slow down or halt their proliferation as a person ages, and that this creates circumstances in which cancer cells can thrive all the better by continuing to divide at full throttle. On this view, replicative cell senescence, far from protecting us from the growth of tumors, creates a breeding ground for mutant cells that evade the normal controls and overrun the tissue because they face no competition from their senescent normal neighbors. The mutations that allow continued proliferation may confer at the same time other cancerous traits, such as genetic instability or a general disregard for cell-cycle controls, leading on to progressively more disordered behavior. In this way, replicative cell senescence in a self-renewing tissue might be expected to favor the genesis of cancer; it could be a part of the reason why cancer is predominantly a disease of old age.

Studies at a molecular level may soon clarify the picture. Later in the chapter, we see that replicative cell senescence in human cells is related to the shortening of telomeres—the repetitive DNA sequences and associated proteins that cap the ends of each chromosome. And we discuss how some cancers may arise from the dangerous ways in which certain mutations can allow cells to escape the block to cell division that normal cells encounter when their telomeres get too short. [↑ TOP](#)

To Metastasize, Malignant Cancer Cells Must Survive and Proliferate in an Alien Environment

Metastasis is the most feared—and least understood—aspect of cancer. By spreading throughout the body a cancer becomes almost impossible to eradicate surgically or by localized irradiation, and thus deadly. Metastasis is itself a multistep process: cells have to break away from the primary tumor, invade local tissues and vessels, and establish new cellular colonies at distant sites. Each of these events is, in itself, fairly complex and the molecular mechanisms involved are not yet clear.

For a cancer cell to metastasize, it must first detach from the parent tumor; key to this escape is an ability to invade neighboring tissues. Such invasiveness is the defining property of malignant tumors, which show a disorganized pattern of growth and ragged borders, with extensions into the surrounding tissue (see, for example, [Figure 23-3](#)). Although invasiveness is not thoroughly understood, it almost certainly requires a disruption of the adhesive

mechanisms that normally keep cells tethered to their proper neighbors.

The next step in the process—escape from the neighborhood of the primary tumor and establishment of colonies in distant tissues—is a complex, slow, and inefficient operation; few cells in the primary tumor achieve it. To metastasize successfully, a cell must penetrate a blood vessel or a lymphatic vessel, cross the basal lamina and the endothelial lining of the vessel so as to enter the circulation, exit from the circulation elsewhere in the body, and survive and proliferate in the new environment in which it finds itself ([Figure 23-15](#)). Many cancers may invade local connective tissues but do not succeed in forming metastases before they are discovered and surgically removed. Only a tiny proportion of malignant cells manage to escape into the circulation; and experiments show that only a tiny proportion of these, less than one in thousands, perhaps one in millions, survive to form metastases. What seems to distinguish cells that are able to establish metastases is their ability to survive and grow after settling in an alien site.

It is thought that normal cells depend on molecular survival signals that are peculiar to their normal environment; when deprived of these signals, they activate their cell death machinery and undergo apoptosis. Cancer cells capable of metastasis are often relatively resistant to apoptosis compared with normal cells and therefore can survive and continue to grow after escaping from their proper home ([Figure 23-16](#)).

In addition to all these requirements, to grow large, a tumor must recruit an adequate blood supply. Thus, angiogenesis, the formation of new blood vessels, is a necessity for growth of both primary tumors and metastases. Although normal tissues have an automatic mechanism to attract an increased blood supply when they require it (as discussed in [Chapter 22](#)), many tumors achieve rapid growth by switching on enhanced production of angiogenic signals. The new blood vessels supply the tumor with nutrients and oxygen, and they may also provide an easier escape route for metastatic cells. [↑ TOP](#)

Six Key Properties Make Cells Capable of Cancerous Growth

Clearly, to be successful as a cancer a cell must acquire a whole range of aberrant properties—a collection of subversive new skills—as it evolves. Different cancers require different combinations of properties. Nevertheless, we can draw up a short list of the key behaviors of cancer cells in general:

1. They disregard the external and internal signals that regulate cell proliferation.
2. They tend to avoid suicide by apoptosis.

3. They circumvent programmed limitations to proliferation, escaping replicative senescence and avoiding differentiation.
4. They are genetically unstable.
5. They escape from their home tissues (that is, they are invasive).
6. They survive and proliferate in foreign sites (that is, they metastasize).

In the later sections of the chapter, we shall examine the mutations and molecular mechanisms that underlie these properties. But first, we must consider the external factors that can help to cause the disease. [↑ TOP](#)

Summary

Cancer cells, by definition, proliferate in defiance of normal controls (that is, they are neoplastic) and are able to invade and colonize surrounding tissues (that is, they are malignant). By giving rise to secondary tumors, or metastases, they become difficult to eradicate surgically. Most cancers are thought to originate from a single cell that has experienced an initial mutation, but the progeny of this cell must undergo further changes, requiring numerous additional mutations, to become cancerous. This phenomenon of tumor progression, which usually takes many years, reflects the unfortunate operation of evolution by mutation and natural selection among somatic cells.

The rational treatment of cancer requires an understanding of the special properties that cancer cells acquire as they evolve, multiply, and spread. These special properties include alterations in cell signaling pathways, enabling the cells in a tumor to ignore the signals from their environment that normally keep cell proliferation under tight control. In this way, the cells are first able to proliferate abnormally in their original tissue and then to metastasize, surviving and proliferating in foreign tissues. As part of the evolutionary process of tumor progression, cancer cells also acquire an abnormal aversion to suicide, and they avoid or break free of programmed limitations to proliferation—including replicative senescence and the normal pathways of differentiation that would otherwise hamper their ability to grow and divide.

Since many mutations are needed to confer this whole collection of bad properties, it is perhaps not surprising to find that nearly all cancer cells are observed to have the additional property of being abnormally mutable, having acquired one or more defects in various aspects of their DNA metabolism. This genetic instability speeds the cell's acquisition of the complex set of alterations that are required for neoplasia and malignancy. [↑ TOP](#)

Figure 23-2. Cancer incidence and mortality in the United States. These figures are for the year 2000. Total new cases diagnosed in that year in the United States were 1,220,000, and total cancer deaths were 552,200. Note that only about half the number of people who develop cancer die of it. In the world as a whole, the five most common cancers are those of the lung, stomach, breast, colon/rectum, and uterine cervix, and the total number of new cancer cases recorded per year is just over 6 million. Skin cancers other than melanomas are not included in figures, since almost all are cured easily and many go unrecorded. (Data from American Cancer Society, Cancer Facts and Figures, 2000.)

Figure 23-6. Evidence from X-inactivation mosaics demonstrates the monoclonal origin of cancers. As a result of a random process that occurs in the early embryo, practically every normal tissue in a woman's body is a mixture of cells with different X chromosomes heritably inactivated (indicated here by the mixture of *red* cells and *gray* cells in the normal tissue). When the cells of a cancer are tested for their expression of an X-linked marker gene, however, they are usually all found to have the same X chromosome inactivated. This implies that they are all derived from a single cancerous founder cell.

Figure 23-9. The stages of progression in the development of cancer of the epithelium of the uterine cervix.

Pathologists use standardized terminology to classify the types of disorder they see, so as to guide the choice of treatment. Schematic diagrams are shown in A-D; sections of cervical epithelium corresponding to these changes are shown in E-H. (A, E) In the normal stratified squamous epithelium, dividing cells are confined to the basal layer. (B, F) In low-grade intraepithelial neoplasia, dividing cells can be found throughout the lower third of the epithelium; the superficial cells are still flattened and show signs of differentiation, but this is incomplete. (C, G) In high-grade intraepithelial neoplasia, cells in all the epithelial layers are proliferating and show no sign of differentiation. (D, H) True malignancy begins when the cells move through or destroy the basal lamina and invade the underlying connective tissue. (Photographs courtesy of Margaret Stanley.)

Figure 23-11. Clonal evolution. A tumor develops through repeated rounds of mutation and proliferation, giving rise eventually to a clone of fully malignant cancer cells. At each step, a single cell undergoes a mutation that enhances cell proliferation, so that its progeny become the dominant clone in the tumor. Proliferation of this clone then hastens occurrence of the next step of tumor progression by increasing the size of the cell population at risk of undergoing an additional mutation.

Figure 23-13. Genetic instability and tumor progression. Cells that maintain an optimum level of genetic instability may be the most successful in the race to form a tumor. (A) In normal cells, the intrinsic amount of genetic instability is low. Thus when normal cells hit a selection barrier—low levels of oxygen or a scarcity of proliferation signals, for example—they are very unlikely to be mutable enough to produce a cell that continues proliferating. (B) In tumor cell precursors, an increased level of genetic instability makes it likely that at least one cell will contain the requisite genetic alteration to pass the selection barrier and continue the process of tumor progression. This genetic instability is retained in the lineage, and it can be measured in the resulting tumor. (C) If the level of genetic instability is too high, many of the cells suffer deleterious mutations and either proliferate much more slowly than their neighbors or are eliminated by cell death. This excessive mutability can lead to extinction of the cell lineage. (Adapted from D.P. Cahill et al., *Trends Cell Biol.* 9:M57–M60, 1999.)

Figure 23-15. Steps in the process of metastasis. This example illustrates the spread of a tumor from an organ such as the lung or bladder to the liver. Tumor cells may enter the bloodstream directly by crossing the wall of a blood vessel, as diagrammed here, or, more commonly perhaps, by crossing the wall of a lymphatic vessel that ultimately discharges its contents (lymph) into the bloodstream. Tumor cells that have entered a lymphatic vessel often become trapped in lymph nodes

along the way, giving rise to lymph-node metastases. Studies in animals show that typically far less than one in every thousand malignant tumor cells that enter the bloodstream will survive to produce a tumor at a new site.

Molecular Biology of the Cell ➔ V. Cells in Their Social Context ➔ 23. Cancer

The Preventable Causes of Cancer

The development of a cancer generally requires many steps, each governed by multiple factors—some dependent on the genetic constitution of the individual, others dependent on his or her environment and way of life. A certain irreducible background incidence of cancer is to be expected regardless of circumstances: mutations can never be absolutely avoided, because they are an inescapable consequence of fundamental limitations on the accuracy of DNA replication, as discussed in Chapter 5. If a human could live long enough, it is inevitable that at least one of his or her cells would eventually accumulate a set of mutations sufficient for cancer to develop.

Nevertheless, there is evidence that avoidable environmental factors play some part in the causation of most cases of the disease. This is demonstrated most clearly by a comparison of cancer incidence in different countries: for almost every cancer that is common in one country, there is another country where the incidence is several times lower (Table 23-1). Because migrant populations tend to adopt the pattern of cancer incidence typical of the host country, the differences appear to be due mostly to environmental, not genetic, factors. From such data it is estimated that 80–90% of cancers should be avoidable, or at least postponable. Unfortunately, different cancers have different environmental risk factors, and a population that happens to escape one such danger is usually exposed to another. This is not, however, inevitable. There are some subgroups whose way of life substantially reduces the total cancer death rate among individuals of a given age. Under the current conditions in the United States and Europe, approximately one in five people die of cancer. But the incidence of cancer among strict Mormons in Utah, for example, is only about half that among Americans in general. Cancer incidence is also low in certain relatively affluent populations in Africa.

Although such observations on human populations indicate that cancer can often be avoided, it has been difficult in most cases to identify the specific environmental risk factors or to establish how they act. We will first look at what has been learned about the external agents that are known to cause cancer. We will then consider some of the triumphs, and difficulties, in finding ways in which human cancer can be prevented. The problem of treatment will be discussed in the last section, after we have examined the molecular biology of the disease.

Many, But Not All, Cancer-Causing Agents Damage DNA

The agents that can cause cancer are many and varied, but the easiest to understand are those that cause damage to DNA, and so generate mutations. These cancer-causing mutagens include chemical carcinogens, viruses, and various forms of radiation—UV light and ionizing radiation such as gamma rays and alpha particles from radioactive decay.

Many quite disparate chemicals have been shown to be carcinogenic when they are fed to experimental animals or painted repeatedly on their skin. Examples include a range of aromatic hydrocarbons and derivatives of them such as aromatic amines; nitrosamines; and alkylating agents such as mustard gas. Although these chemical carcinogens are diverse in structure, they have at least one property in common—they cause mutations. In one popular test for mutagenicity, the carcinogen is mixed with an activating extract prepared from rat liver cells (to mimic the biochemical processing that occurs in an intact animal) and is added to a culture of specially designed test bacteria; the resulting mutation rate of the bacteria is then measured ([Figure 23-17](#)). Most of the compounds scored as mutagenic by this rapid and convenient assay in bacteria also cause mutations or chromosome aberrations when tested on mammalian cells. When mutagenicity data from various sources are analyzed, one finds that the majority of identified carcinogens are mutagens.

A few of these carcinogens act directly on the target DNA, but generally the more potent ones are relatively inert chemically and become damaging only after they have been changed to a more reactive form by metabolic processes—notably by a set of intracellular enzymes known as the cytochrome P-450 oxidases. These enzymes normally help to convert ingested toxins into harmless and easily excreted compounds. Unfortunately, their activity on certain chemicals generates products that are highly mutagenic. Examples of carcinogens activated in this way include the fungal toxin aflatoxin B1 ([Figure 23-18](#)) and benzo[a]-pyrene, a cancer-causing chemical present in coal tar and tobacco smoke. [↑ TOP](#)

The Development of a Cancer Can Be Promoted by Factors That Do Not Alter the Cell's DNA Sequence

Not all substances that favor the development of cancer are mutagens, however. Some of the clearest evidence comes from studies done long ago on the effects of cancer-causing chemicals on mouse skin, where it is easy to observe the stages of tumor progression. Skin cancers can be elicited in mice by repeatedly painting the skin with a mutagenic chemical carcinogen such as benzo[a]pyrene or the related compound dimethylbenz[a]anthracene (DMBA). A single application of the carcinogen, however, usually does not by itself give rise to a tumor or any other obvious lasting abnormality. Yet it does cause

latent genetic damage—mutations that set the stage for a greatly increased incidence of cancer when the cells are exposed either to further treatments with the same substance or to certain other, quite different, insults. A carcinogen that sows the seeds of cancer in this way is said to act as a **tumor initiator**.

Simply wounding skin that has been exposed once to such an initiator can cause cancers to develop from some of the cells at the edge of the wound. Alternatively, repeated exposure over a period of months to certain substances known as **tumor promoters**, which are not themselves mutagenic, can cause cancer selectively in skin previously exposed to a tumor initiator. The most widely studied tumor promoters are *phorbol esters*, such as tetradecanoylphorbol acetate (TPA), which behave as artificial activators of protein kinase C and hence activate part of the phosphatidylinositol intracellular signaling pathway (discussed in [Chapter 15](#)). These substances cause cancers at high frequency only if they are applied after a treatment with a mutagenic initiator ([Figure 23-19](#)).

As one might expect for genetic damage, the hidden changes caused by a tumor initiator are irreversible: thus, they can be uncovered by treatment with a tumor promoter even after a long delay. The immediate effect of the promoter is apparently to stimulate cell division (or to cause cells that would normally undergo terminal differentiation to continue dividing instead). In the region that had previously been exposed to the initiator, this proliferation results in the growth of many small, benign, wartlike tumors called *papillomas*. The greater the prior dose of initiator, the larger the number of papillomas induced; it is thought that each papilloma (at least for low doses of the initiator) consists of a single clone of cells descended from a mutant cell that the initiator has produced. How tumor promoters work is not certain, and different tumor promoters are likely to work in different ways. One possibility is that they simply induce expression of growth-controlling genes that had been mutated before the promoter was applied: a mutation that makes a gene product hyperactive will not show its effects until the gene is expressed. Another possibility is that the promoter temporarily releases the cell from an inhibitory influence that normally overrides the proliferation-inducing effect of the mutation; as a result, the cell is enabled to divide and grow into a large cluster of cells ([Figure 23-20](#)).

A typical papilloma might contain about 10^5 cells. If exposure to the tumor promoter is stopped, almost all the papillomas regress, and the skin regains a largely normal appearance. In a few of the papillomas, however, further changes occur that enable growth to continue in an uncontrolled way, even after the promoter has been withdrawn. These changes seem to originate in an occasional single papilloma cell, at about the frequency expected for spontaneous mutations. In this way, a small proportion of the papillomas progress to become cancers. Thus, the tumor promoter apparently favors the development of cancer by expanding the population of cells that carry an initial mutation: the more such cells there are and the more times they divide, the greater the chance that at least one of them will undergo another mutation

carrying it one step further toward malignancy.

Although naturally occurring cancers do not necessarily arise through the specific sequence of distinct initiation and promotion steps just described, their evolution must be governed by similar principles. They too will evolve at a rate that depends both on the frequency of mutations and on the influences affecting the survival, proliferation, and spread of selected mutant cells. [↑ TOP](#)

Viruses and Other Infections Contribute to a Significant Proportion of Human Cancers

As far as we know, viruses and other infections play no part in the majority of human cancers. However, a small but significant proportion of human cancers, perhaps 15% in the world as a whole, are thought to arise by mechanisms that do involve viruses, bacteria or parasites. The main culprits, as shown in [Table 23-2](#), are the DNA viruses. Evidence for their involvement comes partly from the detection of viruses in cancer patients and partly from epidemiology. Liver cancer, for example, is common in parts of the world (Africa and Southeast Asia) where hepatitis-B viral infections are common, and in those regions the cancer occurs almost exclusively in people who show signs of chronic hepatitis-B infection.

The precise role of a cancer-associated virus is often hard to decipher because there is a delay of many years from the initial viral infection to the development of the cancer. Moreover, the virus is responsible for only one of a series of steps in the progression to cancer, and other environmental factors and genetic accidents are also involved. Like the cancer-causing chemicals we discussed earlier, viruses can either alter a cell's DNA directly or act as tumor promoters. As we shall explain later, DNA viruses frequently carry genes that can subvert the control of cell division in the host cell, causing uncontrolled proliferation. DNA viruses that operate in this manner include the human papillomaviruses ([Figure 23-21](#)); some of these viruses cause warts, while others infect the uterine cervix and are implicated in the development of carcinomas of the cervix.

In some other cancers, viruses seem to have additional, indirect tumor-promoting actions; the hepatitis-B virus may, for example, favor the development of liver cancer by doing damage that provokes cell division in the liver, as well as by altering cell growth control directly. In AIDS, the human immunodeficiency virus (HIV) promotes development of an otherwise rare cancer called Kaposi's sarcoma by destroying the immune system, thereby permitting a secondary infection with a human herpes virus (HHV-8) that has a direct carcinogenic action. Chronic infection with parasites and bacteria may also promote the development of some cancers. For example, infection of the stomach with the bacterium *Helicobacter pylori*, which causes ulcers, appears to be a major cause of stomach cancer. And bladder cancer in some parts of the world is associated with infection by the blood fluke, *Schistosoma*

haematobium, a parasitic flatworm. [↑ TOP](#)

Identification of Carcinogens Reveals Ways to Avoid Cancer

Tobacco smoke is by far the most important environmental cause of cancer in the world today. Other comparably important chemical causes of cancer in humans remain to be identified. It is sometimes thought that the main environmental causes of cancer are the products of a highly industrialized way of life—the rise in pollution, the enhanced use of food additives, and so on—but there is little evidence to support this view. The idea may have come in part from the identification of some highly carcinogenic materials used in industry, such as 2-naphthylamine and asbestos. In fact, except for the increase in cancers caused by smoking, and a remarkable decrease in stomach cancer, the incidence of the most common cancers for individuals of a given age has not changed very much during the course of the twentieth century ([Figure 23-22](#)).

Most of the carcinogenic factors that are known to be significant are by no means peculiar to the modern world. The most potent known carcinogen (by certain assays), and an important cause of liver cancer in Africa and Asia, is aflatoxin B1 (see [Figure 23-18](#)), a compound produced by fungi that naturally contaminate foods such as tropical peanuts. And for women, the risk of cancer is powerfully influenced by the reproductive hormones that circulate in the body at different stages of life. Thus, a striking correlation exists between reproductive history and the occurrence of breast cancer ([Figure 23-23](#)). The reproductive hormones presumably affect breast-cancer incidence through their influence on cell proliferation in the breast. Clearly, when attempting to identify the environmental causes of cancer, we need to keep an open mind.

Epidemiology—the analysis of disease frequency in populations—remains the principal tool for finding environmental causes of human cancer. The approach has enjoyed some notable successes and it promises more to come. Simply by revealing the role of smoking, epidemiology has shown a way to reduce the total cancer death rate in North America and Europe by as much as 30%. The approach works best when applied to a fairly uniform population in which it is easy to distinguish between individuals who were exposed to the agent and those who were not, and when the agent under investigation is responsible for most of the cases of a certain kind of cancer. For example, in the early part of this century, in one British factory, all of the men who had been employed in distilling 2-naphthylamine (and were thereby subjected to prolonged exposure) eventually developed bladder cancer (see [Figure 23-8](#)); the connection was relatively easy to establish because both the chemical and the form of cancer were uncommon in the general population.

In contrast, it is very hard to identify, by epidemiology alone, everyday environmental factors that favor development of common cancers: most of these factors are probably agents to which we are all exposed to some extent,

and many of them probably contribute together to a given cancer's incidence. If, say, eating oranges doubled the risk of colorectal cancer, it is unlikely that we would find it out, unless we had some prior reason to suspect a connection; and, the same goes for the countless other substances that we eat, drink, breathe, and put on our bodies. Even when evidence is obtained that a substance may be carcinogenic, either from epidemiology or from laboratory tests, it may be difficult to decide what level of human exposure is acceptable. Estimating how many cases of human cancer a certain amount of a substance is likely to cause is difficult; balancing this risk against the utility of the substance is more difficult still. For example, certain agricultural fungicides appear to be mildly carcinogenic at high doses in animal tests, but it has been calculated that if they were not used in agriculture the contamination of food by fungal metabolites such as aflatoxin B1 would cause far more cases of cancer than the fungicide residues in food ever could.

Nevertheless, efforts to identify potential carcinogens still have a central place in our struggle with cancer. Prevention of the disease is not only better than a cure; for many types of cancer, it seems also, in our present state of knowledge, to be much more readily attainable. [↑ TOP](#)

Summary

The rate of tumor evolution and progression is accelerated both by mutagenic agents (tumor initiators) and by nonmutagenic agents (tumor promoters) that affect gene expression, stimulate cell proliferation, and alter the ecological balance of mutant and nonmutant cells. The majority of known cancer-causing agents are mutagens, including chemical carcinogens, certain viruses, and various forms of radiation—such as UV light and ionizing radiation. Because many factors contribute to the development of a given cancer—some of which are under our control—a large proportion of cancers are in principle preventable.

We remain largely ignorant of the principal environmental factors affecting cancer incidence. Of the environmental risk factors that have been identified, however, many can be avoided. These include smoking tobacco and falling prey to infection with cancer-causing viruses such as papillomaviruses or hepatitis B. Epidemiology can be a powerful tool for identifying such causes of human cancer and revealing ways to prevent the disease. The approach does not require knowing how cancer-causing agents work, and it can uncover factors that are not simply mutagens, such as viruses and certain patterns of child-bearing. [↑ TOP](#)

Figure 23-17. The Ames test for mutagenicity. The test uses a strain of *Salmonella* bacteria that require histidine in the medium because of a defect in a gene necessary for histidine synthesis. Mutagens can cause a further change in this gene that reverses the defect, creating revertant bacteria that do not require histidine. To increase the sensitivity of the test, the bacteria also have a defect in their DNA repair machinery that makes them especially susceptible to agents that damage DNA. A majority of compounds that are mutagenic in tests such as this are also carcinogenic and vice versa.

Figure 23-18. Metabolic activation of a carcinogen. Many chemical carcinogens have to be activated by a metabolic transformation before they will cause mutations by reacting with DNA. The compound illustrated here is *aflatoxin B1*, a toxin from a mold (*Aspergillus flavus oryzae*) that grows on grain and peanuts when they are stored under humid tropical conditions. It is thought to be a contributory cause of liver cancer in the tropics and is associated with characteristic mutations of the *p53* gene (discussed later in this chapter).

Figure 23-23. Effects of childbearing on the risk of breast cancer. The relative probability of breast cancer developing at some time in a woman's life is plotted as a function of the age at which she gives birth to her first child. The graph shows the value of the probability relative to that for a childless woman. The longer the period of exposure to reproductive hormones up to birth of the first child, the greater the risk. It is thought that the first full-term pregnancy may result in a permanent change in the state of differentiation of the cells of the breast, altering their subsequent responses to hormones. Several other lines of epidemiological evidence also support the view that exposure to certain combinations of reproductive hormones, especially estrogen, can promote development of breast cancer. (From J. Cairns, *Cancer: Science and Society*. San Francisco: W.H. Freeman, 1978. After B. MacMahon, P. Cole, and J. Brown, *J. Natl. Cancer Inst.* 50:21–42, 1973.)

Table 23-2. Viruses Associated with Human Cancers

VIRUS	ASSOCIATED TUMORS	AREAS OF HIGH INCIDENCE
<i>DNA Viruses</i>		
Papovavirus family		
Papillomavirus (many distinct strains)	warts (benign) carcinoma of the uterine cervix	worldwide worldwide
Hepadnavirus family		
Hepatitis-B virus	liver cancer (hepatocellular carcinoma)	Southeast Asia, tropical Africa
Herpesvirus family		
Epstein-Barr virus	Burkitt's lymphoma (cancer of B lymphocytes) nasopharyngeal carcinoma	West Africa, Papua New Guinea southern China, Greenland
<i>RNA viruses</i>		
Retrovirus family		
Human T-cell leukemia virus type I (HTLV-1)	adult T-cell leukemia/lymphoma	Japan, West Indies
Human immuno-deficiency virus (HIV, the AIDS virus)	Kaposi's sarcoma	Central and Southern Africa

For all the above viruses, the number of people infected is much larger than the numbers who develop cancer: the viruses must act in conjunction with other factors. Moreover, some of the viruses contribute to cancer only indirectly; for example, HIV, by upsetting normal cell-mediated immune defenses, allows endothelial cells to be transformed by another virus (a type of herpesvirus) and thrive as a tumor instead of being destroyed by the immune system.

Finding the Cancer-Critical Genes

Cancer is a genetic disease: it results from mutations in somatic cells. To understand it at a molecular level, we need to identify the relevant mutations and to discover how they give rise to cancerous cell behavior. Finding the mutations is easy in one respect: the mutant cells are favored by natural selection and call attention to themselves by giving rise to tumors. The hard task then begins: how are the genes with the carcinogenic mutations to be identified among all the other genes in the cancerous cells? A similar needle-in-haystack problem arises in any search for a gene underlying a given mutant phenotype, but for cancer the task is particularly complex. A typical cancer depends on a whole set of mutations—usually a somewhat different set in each individual patient—and introduction of any single one of these into a normal cell is usually not enough to make it cancerous. This genetic cooperation makes it hard to test the significance of mutations on which suspicion falls. To make matters worse, most cancer cells will contain mutations that are accidental by-products of genetic instability, and it can be difficult to distinguish these from the mutations that have a causative role in the disease.

Despite these difficulties, many genes that are repeatedly altered in human cancer have been identified—more than 100 of them—although it is clear that many more remain to be discovered. We will call such genes, for want of a better term, **cancer-critical genes**, meaning all genes whose mutation contributes to the causation of cancer. Our knowledge of these genes has accumulated piecemeal through many different and sometimes circuitous approaches, ranging from investigations of embryonic development to studies of cancer-causing infections in chickens. Analyses of exceptional but highly revealing forms of the disease have played a large part.

In this section, we discuss both the methods used for identifying cancer-critical genes and the varied kinds of mutations that occur in them in the development of cancer.

Different Methods Are Used to Identify Gain-of-Function and Loss-of-Function Mutations

Cancer-critical genes are grouped into two broad classes, according to whether

Figure 23-29. Six ways of losing the...

the cancer risk arises from too much activity of the gene product, or too little. Genes of the first class, for which a gain-of-function mutation drives a cell toward cancer, are called proto-oncogenes; their mutant, overactive forms are called oncogenes. Genes of the second class, for which a loss-of-function mutation creates the danger, are called tumor suppressor genes.

As we will see, both kinds of mutations can have similar effects in enhancing cell proliferation and survival. Thus, from the point of view of a cancer cell, oncogenes and tumor suppressors—and the mutations that affect them—are flip sides of the same coin. The techniques needed to find these genes, however, are different, and are dictated by whether they are made overactive or underactive in cancer.

Mutation of a single copy of a proto-oncogene can have a dominant, growth-promoting effect on a cell (Figure 23-24A). Thus the oncogene can be detected by its effect when it is *added*—by DNA transfection, for example, or through infection with a viral vector—to the genome of a suitable type of tester cell. In the case of the tumor suppressor gene, on the other hand, the cancer-causing mutations are generally recessive: both copies of the normal gene must be removed or inactivated in the diploid somatic cell before an effect is seen (Figure 23-24B). This calls for a different approach, to discover what is missing.

In some cases, a specific gross chromosomal abnormality, visible under the microscope, is repeatedly associated with a particular type of cancer. This can give a clue to the location of either an oncogene that is activated as a result of the chromosomal rearrangement (as in the example of the chromosomal translocation responsible for chronic myelogenous leukemia, mentioned earlier) or a tumor suppressor gene that is deleted; but the types of chromosomal abnormality involved in the two cases, and the circumstances in which they are typically encountered, are again different. [↑ TOP](#)

Oncogenes Are Identified Through Their Dominant Transforming Effects

Traditionally, geneticists identify genes by studying patterns of inheritance in families of individuals who show some heritable trait. To find where a mutation responsible for the trait lies in the genome, one looks for genetic linkage between this trait and genetic markers whose chromosomal position is known. This approach exploits an effect of sexual reproduction: genes that lie close to one another tend to be inherited together, whereas genes that are further apart are often separated by recombination during meiosis. In this way, a disease-causing mutation can be located by determining how far it lies from other genetic markers (see [Chapter 8](#) for a detailed discussion).

Cancer cells do not reproduce sexually, so geneticists must use other methods

to track down the mutations that make cancer cells different from their normal neighbors in the body. For oncogenes, a direct and conceptually simple (though laborious) approach is to scan the genome of the cancer cell for segments of DNA that will, when introduced into cells of a suitable tester cell line, drive them toward cancerous behavior. A mouse-derived fibroblast cell line is a convenient source of tester cells for the assay; these cells, which were previously selected to thrive in culture, are thought to already contain genetic alterations that take them part of the way toward malignancy. For this reason, addition of a single oncogene can be enough to produce a dramatic effect.

To detect an oncogene in this way, DNA is extracted from tumor cells, broken into fragments, and introduced into these fibroblasts in culture. If any of the fragments contains an oncogene, small colonies of abnormally proliferating—so-called 'transformed'—cells may begin to appear. Each of these colonies will be composed of a clone of cells that originated from a single cell whose growth was promoted by the added gene. Because they have been released from some of the social controls on cell division, the transformed cells outgrow normal ones, piling up in layer upon layer in the culture dish as they proliferate ([Figure 23-25](#)).

This assay, applied to DNA from human tumors, led to the first direct identification of an oncogenic mutation in a human cancer. Several overactive growth-promoting genes were identified by isolating and sequencing the DNA fragments that had been transferred to these transformed cells. The first of these genes to be sequenced was a mutant version of the ***Ras*** gene, which is now known to be mutated in about one in four human tumors.

This discovery was all the more dramatic because, shortly beforehand, a mutated *Ras* gene had been found to be the tumor-causing gene in a retrovirus that causes sarcomas in rodents. Retroviruses, we now know, are capable of picking up, at random, fragments of genetic material from their animal hosts and ferrying them from one infected individual to another. Occasionally, a proto-oncogene is picked up, in a damaged or misregulated form that turns it into an oncogene. Infection with a virus that carries such a cargo can trigger tumors in some animal species, and a large number of oncogenes were first discovered in this way.

Twenty years ago, the discovery of the same mutant gene in human tumor cells and in an animal virus that causes tumors was electrifying. The suggestion that cancers are caused by mutations in a limited number of cancer-critical genes made unraveling the exact nature of cancer seem a soluble scientific problem, and it helped to launch a transformation in our understanding of the molecular biology of cancer.

As we saw in [Chapter 15](#), normal Ras proteins are monomeric GTPases that help to transmit signals from growth factor receptors on the cell surface. The point mutations found in *Ras* genes isolated from human tumors generate a

hyperactive Ras protein that persists abnormally in its active state—transmitting an inappropriate signal for cell proliferation. Because this type of mutation makes a gene product hyperactive, the effect is dominant—only one of the cell's two gene copies needs to undergo the change. The *Ras* genes are mutated in a wide range of human cancers, and they remain one of the most important examples of cancer-critical genes. [↑ TOP](#)

Tumor Suppressor Genes Can Sometimes Be Identified by Study of Rare Hereditary Cancer Syndromes

Given a cancer cell, identifying a gene that has been inactivated requires a different strategy than finding a gene that has become hyperactive: one cannot, for example, use a cell transformation assay to identify something that simply is not there. Thus, the search for tumor suppressor genes has taken a route quite different from that followed in the hunt for oncogenes. The key insight that led to the discovery of the first tumor suppressor gene came from studies of a rare type of human cancer, **retinoblastoma**, which arises from cells in the body that are converted to a cancerous state by an unusually small number of mutations. As often happens in biology, the discovery arose from examination of a special case, but it turned out to be of universal relevance.

Retinoblastoma occurs in childhood; tumors develop from neural precursor cells in the immature retina. About one child in 20,000 is afflicted. There are two forms of the disease, one hereditary, the other not. In the hereditary form, multiple tumors usually arise independently, affecting both eyes; in the non-hereditary form only one eye is affected, and by only one tumor. Some individuals with hereditary retinoblastoma have a visibly abnormal karyotype, with a deletion of a specific band on chromosome 13. Deletions of this same locus are also encountered in tumor cells from some patients with the nonhereditary disease, suggesting that the cancer may be caused by loss of a critical gene in that chromosomal region.

Using the known location of the chromosomal deletion associated with retinoblastoma, it was possible to clone and sequence the gene whose loss appears to be critical for development of the cancer—the *Rb* gene. As would be predicted, in those who suffer from the hereditary form of the disease, a deletion or loss-of-function mutation occurs in one copy of the *Rb* gene in every cell of the body. Thus, these cells are predisposed to becoming cancerous, but are not actually cancerous so long as they retain one good copy of the gene. The retinal cells that do become cancerous are defective in both copies of *Rb* because a somatic mutation has occurred, in addition to the original inherited mutation, and has eliminated the remaining good copy. In patients with the nonhereditary form of the disease, by contrast, the noncancerous cells show no defect in either copy of *Rb*, while the cancerous cells are again defective in both copies. These nonhereditary retinoblastomas are very rare, because they require the coincidence of two somatic mutations in a single retinal cell lineage, so as to destroy both copies of the *Rb* gene ([Figure](#)

23-26).

The *Rb* gene subsequently turned out to much more than a gene mutated in a rare childhood tumor: it is also missing in several common types of cancer, including carcinomas of lung, breast, and bladder. These more common cancers arise by a more complex series of genetic changes than does retinoblastoma, and they make their appearance later in life and in other tissues of the body. But in all of them, it seems, loss of *Rb* is frequently a major step in the progression toward malignancy. The *Rb* gene encodes the Rb protein, which is a universal regulator of the cell cycle that is normally expressed in almost all the cells of the body (see [Figure 17-30](#)). Because it acts as one of the main brakes on progress through the cell-division cycle, the loss of Rb can allow cells to enter the cell division cycle inappropriately, as we shall discuss in the section on the molecular basis of cancer cell behavior. [↑ TOP](#)

Tumor Suppressor Genes Can Be Identified Even Without Clues from Heritable Cancer Syndromes

Hereditary cancer syndromes such as retinoblastoma are very rare, as we have already emphasized, and only a few—though important—tumor suppressor genes have been discovered by studying them. Where there is no such clue from a hereditary syndrome, we face the arduous task of identifying tumor suppressor genes simply by virtue of their absence from tumor cells. This involves comparing the tumor cells with non-cancerous cells from the same patient and discovering what exactly, out of the 3 billion nucleotides of the human genome, is missing or functionally defective. Because of the genetic instability of cancer cells, there is usually a great deal missing. Most of the defects are random and accidental by-products of the genetic instability. The tumor suppressor genes can only be identified by the criterion that they are repeatedly missing or defective in many independent cases of the cancer.

Gene loss often occurs by deletion of a relatively large segment of a chromosome. As a result, one copy of a tumor suppressor gene in a cancer cell may, for example, undergo an inactivating point mutation, while a gross deletion eliminates the other copy along with some neighboring genes (deletion of a large cluster of genes on both chromosomes is likely to kill the cell). The large defect on one chromosome makes detection of the loss much easier.

One deletion detection strategy takes advantage of the normal human genetic variation that makes the maternal and paternal chromosome sets distinguishably different. On average human DNA sequences differ—that is, we are heterozygous—at roughly one in every thousand nucleotides. Where a large segment of one chromosome has been lost, there is consequently a *loss of heterozygosity*: only one version of each variable DNA sequence in that neighborhood remains. A huge number—over a million—common sites of heterozygosity in the human genome have been mapped as part of the Human

Genome Project: each of these sites is characterized by a specific DNA sequence that is known to be *polymorphic*—that is, to occur commonly in two or more slightly different versions in the human population. Given a sample of tumor DNA, one can check which of the versions of these polymorphic sequences are present. The same can be done with a sample of DNA from non-cancerous tissue from the same patient, for comparison. Absence of heterozygosity throughout a region of the genome containing many polymorphic sites, or loss of a genetic marker sequence that is seen in the non-cancerous control DNA, points the way toward a chromosomal region that has been deleted.

Techniques for large-scale DNA analysis and for the detection of deletions and other mutations are advancing rapidly, and they can be expected to add many more tumor suppressor genes to the present catalog. [↑ TOP](#)

Genes Mutated in Cancer Can Be Made Overactive or Underactive in Many Ways

We now know of at least 100 cancer-critical genes that can be converted into oncogenes by an activating mutation. The collection of genes whose absence or inactivation leads toward cancer, the tumor suppressor genes, is smaller but also growing. The ways in which genes of either class can be mutated to make them more—or less—active are enormously varied: as we might expect, any genetic accident that can increase, decrease, or change the activity of a gene is likely to be found somewhere in the increasingly complex catalogue of gene changes that occur in cancer.

The types of genetic alterations that can make a cancer-critical gene into an oncogene fall into three basic categories, as summarized in [Figure 23-27](#). The gene may be altered by a small change in sequence such as a point mutation, by a larger-scale change such as a partial deletion, or by a chromosomal translocation that involves the breakage and rejoining of the DNA helix. These changes can occur in the protein-coding region so as to yield a hyperactive product, or they can occur in adjacent control regions so that the gene is simply expressed at concentrations that are much higher than normal. Alternatively, the cancer-critical gene may be overexpressed because extra copies are present due to *gene amplification* events caused by errors in DNA replication ([Figure 23-28](#)).

Specific types of abnormality are characteristic of particular genes and of the responses to particular carcinogens. For example, 90% of the skin tumors evoked in mice by the tumor initiator dimethylbenz[a]anthracene (DMBA) have an A-to-T alteration at exactly the same site in a mutant *Ras* gene; presumably, of the mutations caused by DMBA, only those at this site efficiently activate skin cells to form a tumor.

The receptor for epidermal growth factor (EGF), on the other hand, can be

activated by a deletion that removes part of its extracellular domain. These mutant receptors are able to form active dimers even in the absence of EGF, and thus they produce a stimulatory signal inappropriately, like a faulty doorbell that rings even when nobody is pressing the button. Such mutations are found in many human brain tumors of the type called glioblastomas.

Members of the *Myc* proto-oncogene family, on the other hand, are not usually activated by mutations in the protein coding region; instead the genes are overexpressed or amplified (see [Figure 23-28](#)). In normal cells, the *Myc* protein acts in the nucleus as a signal for cell proliferation, as discussed in [Chapter 17](#); excessive quantities of *Myc* can cause the cell to proliferate in circumstances where a normal cell would halt. Although *Myc* is frequently amplified in cancers, it can also be made active by a chromosomal translocation. As a result of this rearrangement, powerful gene regulatory sequences are placed inappropriately next to the *Myc* protein coding sequence, producing unusually large amounts of *Myc* mRNA. For example, in Burkitt's lymphoma a translocation brings the *Myc* gene under the control of sequences that normally drive the expression of antibodies in B cells. As a result, the mutant B cells proliferate to excess and form a tumor. Similar specific chromosome translocations are common in lymphomas and leukemias.

Tumor suppressor genes can also be inactivated in many different ways, with different combinations of genetic mishaps coming together to eliminate or cripple both gene copies. The first copy may, for example, be lost by a small chromosomal deletion or inactivated by a point mutation. Even epigenetic changes can inactivate a tumor suppressor gene: for example, its promoter can become methylated or the gene packed into heterochromatin, effectively shutting down gene expression. The second copy may be inactivated in a similar way, but more commonly it is eliminated by a less specific mechanism: the chromosome carrying the remaining normal copy may be lost from the cell, or the normal gene can be replaced by a mutant version through mitotic recombination or gene conversion. The range of possibilities for losing the remaining good copy of a tumor suppressor gene is summarized, using the *Rb* gene as an example, in [Figure 23-29](#). [↑ TOP](#)

The Hunt for Cancer-Critical Genes Continues

The sequencing of the human genome has opened up new avenues toward the systematic discovery of cancer-critical genes. It is now possible in principle to draw up a practically complete list of the 30,000-odd genes in the human genome and to examine every one of them in a given cancer cell line, looking for potentially significant abnormalities, through automated analysis of either the mRNA that the cells produce or their genomic DNA. By applying this procedure to a reasonable number of different cancers, it should be possible to identify the genes that repeatedly undergo mutation in cancer. To carry out such a project in an exhaustive and systematic way is an enormously costly proposition, but not impossibly so, since less than 2% of the human genome

actually codes for proteins. Such an effort is already under way. At the same time, a collaborative enterprise has begun to create an accessible central clearing-house for information about cancer-critical genes—their sequences, mutations, and expression profiles in a variety of cancerous and normal cells. This accumulation of data should lead eventually to an exhaustive catalog of the genes whose mutations contribute to cancer.

To search for cancer-critical genes in the ways we have described, there is in principle no need at the outset to know their normal functions or to understand how mutations in them cause cancer. The strategy, as in a genetic screen for genes involved in any other process, is first to find the culprits, then to work out how they commit their crimes. As our understanding of cell biology improves, however, it becomes easier to guess which genes are likely suspects, and to use these functional clues to track them down. The task of finding the genes is therefore closely entangled with the problem of discovering what they do. This is the topic of the next section. [↑ TOP](#)

Summary

Cancer-critical genes in general can be classified into two groups, according to whether the dangerous mutations in them are those that cause loss of function or those that cause gain of function. Loss-of-function mutations of tumor suppressor genes relieve cells of inhibitions that normally help to hold their numbers in check; gain-of-function mutations of proto-oncogenes stimulate cells to increase their numbers when they should not. These latter mutations have a dominant effect, and the mutant genes, known as oncogenes, are sometimes identified by their ability to drive a specialized line of tester cells toward cancerous proliferation. Many were first discovered because they cause cancer in animals when they are introduced by infection with a viral vector that has picked up genetic material from a previous host cell. Oncogenes can also be located by examining human cancer cells for genes targeted by activating mutations or by the chromosomal translocations that can signal the presence of a cancer-critical gene.

Mutations in tumor suppressor genes are generally recessive in their effects on the individual cell: there is no loss of control until both gene copies are put out of action. Current methods for finding these genes depend on scanning the genomes of cancer cells for signs of gene loss, often manifest as a loss of heterozygosity in a specific chromosomal region. Another approach has been to study cancers that run in families. Though these hereditary forms of cancer are rare, they have led to the discovery of tumor suppressor genes whose loss is a common feature of many cancers. Such cancer-prone individuals often inherit one defective and one functional gene copy of a tumor suppressor gene; they have an increased predisposition toward developing cancer because a single mutation in a somatic cell is enough, with the inherited mutation, to create a cell that totally lacks the tumor suppressor gene function. The recent sequencing of the human genome and the availability of increasingly powerful tools for systematically searching DNA for significant mutations should soon

lead to a much more complete catalog of cancer-critical genes. [↑ TOP](#)

Figure 23-24. Cancer-critical genes fall into two readily distinguishable categories, dominant and recessive. Oncogenes act in a dominant manner: a gain-of-function mutation in a single copy of the cancer-critical gene can drive a cell toward cancer. Tumor suppressor genes, on the other hand, generally act in a recessive manner: the function of both alleles of the cancer-critical gene must be lost to drive a cell toward cancer. In this diagram, activating mutations are represented by solid red boxes, inactivating mutations by hollow red boxes.

Figure 23-28. Chromosomal changes in cancer cells reflecting gene amplification. In these examples, the numbers of copies of a *myc* proto-oncogene have been amplified. Amplification of oncogenes is common in carcinomas and is often visible as a curious change in the karyotype: the cell is seen to contain additional pairs of miniature chromosomes—so-called *double minute chromosomes*—or to have a *homogeneously staining region* interpolated in the normal banding pattern of one of its regular chromosomes. Both these aberrations consist of massively amplified numbers of copies of a small segment of the genome. The chromosomes are stained with a red fluorescent dye, while the multiple copies of the *Myc* gene are detected by *in situ* hybridization with a yellow fluorescent probe. (A) Karyotype of a cell in which the *Myc* gene copies are present as double minute chromosomes (paired yellow specks). (B) Karyotype of a cell in which the multiple *Myc* gene copies appear as a homogeneously staining region (yellow) interpolated in one of the regular chromosomes. (Ordinary single-copy *myc* genes can be detected as tiny yellow dots elsewhere in the genome.) (Courtesy of Denise Sheer.)

The Molecular Basis of Cancer-Cell Behavior

Oncogenes and tumor suppressors—and the mutations that affect them—are different beasts from the point of view of the cancer gene hunter. But from a cancer cell's point of view they are two sides of the same target. The same kinds of effects on cell behavior can result from mutations in either class of genes, because most of the control mechanisms in the cell involve both inhibitory (tumor suppressor) and stimulatory (proto-oncogene) components. In terms of function, the important distinction is not the distinction between a tumor suppressor and a proto-oncogene, but between genes lying in different biochemical and regulatory pathways.

Some of the pathways important in cancer carry signals from a cell's environment (as discussed in [Chapter 15](#)); others are responsible for the cell's internal programs, such as those that control the cell cycle or cell death (discussed in [Chapter 17](#)); still others govern the cell's movements and mechanical interactions with its neighbors (discussed in [Chapter 19](#)). The various pathways are linked and interdependent in complex ways. Much of what we know about them has been learned as a byproduct of cancer research; conversely, study of these basic aspects of cell biology has transformed our understanding of cancer.

In the first section of this chapter, we summarized in general terms the properties that make a cancer cell a cancer cell and listed the kinds of misbehavior a cancer cell displays. In this section, we consider how each of the characteristic properties arises from mutations that have been identified in cancer-critical genes affecting specific regulatory pathways. For some parts of this problem the answers are straightforward. For other parts, large mysteries remain.

We begin with a brief general discussion of how we determine the cellular function of cancer-critical genes. We then review what is known about how these cancer-critical genes control the relevant cell behaviors. Finally, we turn to the development of colon cancer as an example of how tumors evolve through the accumulation of mutations that lead from one pattern of bad behavior to another that is worse.

Studies of Developing Embryos and Transgenic Mice Help to Uncover the Function of Cancer-Critical Genes

Given a gene that is mutated in a cancer, we need to understand both how the gene functions in normal cells and how mutations in the gene contribute to the aberrant behaviors characteristic of cancer cells. When *Rb* was originally cloned, for example, all that was known was that it was deleted in a cancer. In the case of *Ras*, the mutant gene was known to direct cells to proliferate excessively and inappropriately in culture, but this observation did not reveal how the Ras protein functions in normal or cancer cells. In both cases, cancer research was the starting point for studies that revealed the key role of these gene products in normal cells—*Rb* as a cell-cycle regulator, *Ras* as a central component of cell-signaling pathways.

Today, we know much more about cells, so that when a new gene is identified as critical for cancer, it often turns out to be familiar from studies in another context. For example, many oncogenes and tumor suppressor genes are found to be homologs of genes already known for their role in embryonic development. Examples include components of practically all the major developmental signaling pathways through which cells communicate (discussed in [Chapters 15](#) and [21](#)): the Wnt, Hedgehog, TGF β , Notch, and receptor tyrosine kinase signaling pathways all include important cancer-critical genes—with *Ras* being part of the last of these pathways.

In hindsight, this is no surprise. As we saw in [Chapter 22](#), the same signaling mechanisms that control embryonic development operate in the normal adult body to control cell turnover and maintain homeostasis. Both the development of a multicellular animal and the maintenance of its adult structure depend on cell-cell communication and on regulated cell proliferation, cell differentiation, cell death, cell movement, and cell adhesion—in other words, on all the aspects of cell behavior whose derangement underlies cancer. Developmental biology, often using model animals such as *Drosophila* and *C. elegans*, thus provides a key to the normal functions of many cancer-critical genes.

Ultimately, however, we want to know what mutations in these genes do to cells in the tissues that give rise to the cancer. A certain amount of information can be obtained by studying cells *in vitro* or by examining human cancer patients. But to investigate how mutations in various cancer-critical genes affect tissues in a whole organism, the transgenic mouse has proved particularly useful.

Transgenic mice that carry an oncogene in all their cells can be generated by methods described in detail in [Chapter 8](#). Oncogenes introduced in this way may be expressed in many tissues or in only a select few, according to the tissue specificity of the associated regulatory DNA. Studies of such transgenic animals reveal that, even in mice, a single oncogene is not usually sufficient to turn a normal cell into a cancer cell. Typically, in mice that are endowed with a

Myc or *Ras* oncogene, some of the tissues that express the oncogene grow to an exaggerated size, and over time occasional cells undergo further changes to give rise to cancers. The vast majority of the cells in the transgenic mouse that express the *Myc* or *Ras* oncogene, however, do not give rise to cancers, showing that the single oncogene is not enough to cause malignancy. From the point of view of the whole animal, the inherited oncogene, nevertheless, is a serious menace because it increases the risk of developing cancer. Mice that express more than one oncogene can be generated by mating a pair of transgenic mice—one carrying a *Myc* oncogene, the other carrying a *Ras* oncogene, for example. These offspring develop cancers at a much higher rate than either parental strain ([Figure 23-30](#)), but again the cancers originate as scattered isolated tumors among noncancerous cells. Thus, even with these two expressed oncogenes, the cells must undergo further, randomly generated changes to become cancerous.

Just as activated oncogenes can be introduced into mouse tissues, so tumor suppressor genes can be inactivated by 'knocking out' the gene in the mouse using reverse genetic techniques (see [Figure 8-74](#)). Several tumor suppressor genes have been knocked out in mice, including *Rb*. As anticipated, many of the mutant strains that are missing one copy of a tumor suppressor gene are cancer prone. Deletion of both copies often leads to death at an embryonic stage, reflecting the essential roles these genes play during normal development. To bypass this block and see the effect of homozygous mutations in an adult tissue, one can use the methods described in [Chapter 8](#) to create conditional mutations, such that only one tissue—say the liver—displays the defect. In these ways, transgenic mice have become a key source of information as to the mechanisms of tumor formation. We shall see later that they also provide important models for the development of new cancer therapies. [↑ TOP](#)

Many Cancer-Critical Genes Regulate Cell Division

Most cancer-critical genes code for components of the pathways that regulate the social behavior of cells in the body—in particular, the mechanisms by which signals from a cell's neighbors can impel it to divide, differentiate, or die ([Figure 23-31](#)). In fact, many of the components of cell-signaling pathways were first identified through searches for cancer-causing genes, and a full list of proto-oncogene products and tumor suppressors includes examples of practically every type of molecule involved in cell signaling—secreted proteins, transmembrane receptors, GTP-binding proteins, protein kinases, gene regulatory proteins, and so on (discussed in detail in [Chapter 15](#)). Many cancer mutations alter signal pathway components in a way that causes them to deliver proliferative signals even when more cells are not needed, switching on cell growth, DNA replication, and cell division inappropriately. Mutations that inappropriately activate a receptor tyrosine kinase, such as the EGF receptor, or proteins in the Ras family, which lie downstream from such growth factor receptors, act in this way.

Other signaling pathways can function to inhibit cell division, the best known example being the antigrowth effect of the TGF β family of signaling proteins. Loss of growth inhibition through TGF β -mediated pathways contributes to the genesis of several types of human cancers. The receptor TGF β -RII is found to be mutated in some cancers of the colon and Smad4—a key intracellular signal transducer in the pathway—is inactivated in cancers of the pancreas and some other tissues.

Ultimately, the cancer-critical genes that regulate cell division exert their effects by acting on the central cell-cycle control machinery (see [Figure 17-41](#)). Not surprisingly, mutations in this machinery feature prominently in many cancers. As described in [Chapter 17](#), a key point at which cells make the decision to replicate their DNA and enter the cell division cycle is thought to be controlled by the Rb protein, the product of the tumor suppressor gene *Rb*. Rb serves as a brake that restricts entry into S phase by binding to gene regulatory proteins needed to express genes whose products are required for progress round the cycle. Normally, this inhibition by Rb is relieved at the appropriate time by phosphorylation of Rb, which causes it to release its inhibitory grip.

Many cancer cells proliferate inappropriately by eliminating Rb entirely, as we have already seen. Other tumors achieve the same endpoint by acquiring mutations in other components of the Rb regulatory pathway ([Figure 23-32](#)). Thus, in normal cells, a complex of cyclin D1 and the cyclin-dependent kinase Cdk4 (G₁-Cdk) stimulates progression through the cell cycle by phosphorylating Rb (see [Figure 17-30](#)). The p16 (INK4) protein—which is produced when cells are stressed—inhibits cell-cycle progression by preventing the formation of an active cyclin D1-Cdk4 complex. Some glioblastomas and breast cancers are found to have amplified the genes encoding Cdk4 or cyclin D1, thus favoring cell proliferation. And deletion or inactivation of the *p16* gene is common in many forms of human cancer. In cancers where it is not inactivated by mutation, this gene is often silenced by methylation of its regulatory DNA.

The variety of ways in which the machinery of cell-cycle control can be altered in cancer illustrates two important points. First, it explains why individual cases of a particular cancer showing the same symptoms may arise from different mutations: in many cases several alternative mutations will have much the same effect on cell proliferation. Second, it reinforces the point that there is no fundamental difference in the processes that are affected by oncogenes—which become activated by mutation—and those affected by tumor suppressor genes—which become inactivated. These two classes of cancer-critical genes merely differ in whether they play a stimulatory or inhibitory role in a pathway (see also [Figure 23-31](#)).  [TOP](#)

Mutations in Genes That Regulate Apoptosis Allow Cancer

Cells to Escape Suicide

To achieve net cell proliferation, it is necessary not only to drive cells into division, but also to keep cells from committing suicide by apoptosis. There are many normal situations in which cells proliferate continuously, but the cell division is exactly balanced by cell loss. In the germinal centers of lymph nodes, for example, B cells proliferate rapidly but most of their progeny are eliminated by apoptosis. Apoptosis is thus essential in maintaining the normal balance of cell births and deaths in tissues that undergo cell turnover. It also has a vital role in the cellular reaction to damage and disorder. As described in [Chapter 17](#), cells in a multicellular organism commit suicide when they sense that something has gone wrong—when their DNA is severely damaged or when they are deprived of survival signals that tell them they are in their proper place. Resistance to apoptosis is thus a key characteristic of malignant cells, essential for enabling them to increase in number and survive where they should not.

A number of mutations that inhibit apoptosis have been found in tumors. One protein that blocks apoptosis, called Bcl-2, was discovered because it is the target of a chromosome translocation in a B-cell lymphoma. The effect of the translocation is to place the *Bcl-2* gene under the control of a regulatory element that drives overexpression, which allows survival of B lymphocytes that would normally have died.

Of all the cancer-critical genes involved in control of apoptosis, however, there is one that is implicated in cancers in an exceptionally wide range of tissues. This gene, called *p53*, stands at a crucial intersection in the network of pathways governing a cell's responses to DNA damage and other stressful mishaps. Control of apoptosis is only part of the gene's function—though a very important part. As we shall now explain, when *p53* is defective, genetically damaged cells do not merely fail to die; worse still, they wantonly continue to proliferate, accumulating yet more genetic damage that can lead toward cancer. [↑ TOP](#)

Mutations in the *p53* Gene Allow Cancer Cells to Survive and Proliferate Despite DNA Damage

The *p53* gene—named for the molecular mass of its protein product—may be the most important gene in human cancer. This tumor suppressor gene is mutated in about half of all human cancers. What makes *p53* so critical? The answer lies in its triple involvement in cell-cycle control, in apoptosis, and in maintenance of genetic stability—all aspects of the fundamental role of the *p53* protein in protecting the organism against cellular damage and disorder.

In contrast with Rb, very little *p53* protein is found in most of the cells of the body under normal conditions. In fact, *p53* is not required for normal development: transgenic mice in which both copies of the gene have been

knocked out appear normal in all respects except one—they usually develop cancer by the age of 3 months. These observations suggest that p53 may have a function that is required only occasionally or in special circumstances. Indeed, when normal cells are deprived of oxygen or exposed to treatments that damage DNA, such as ultraviolet light or gamma rays, they raise their concentration of p53 protein by reducing the normally rapid rate of degradation of the molecule. The p53 response is seen also in cells where oncogenes such as *Ras* and *Myc* are active, generating an abnormal stimulus for cell division.

In all these cases, the high level of p53 protein acts to limit the harm done. Depending on circumstances and the severity of the damage, the p53 may either drive the damaged or mutant cell to commit suicide by apoptosis (see p. 1013)—a relatively harmless event for the multicellular organism—or it may trigger a mechanism that bars the cell from dividing so long as the damage remains unrepaired. The protection provided by p53 is an important part of the reason why mutations that activate oncogenes such as *Ras* and *Myc* are not enough by themselves to create a tumor.

As discussed in [Chapter 17](#), the p53 protein exerts its cell-cycle effects, in part at least, by binding to DNA and inducing the transcription of *p21*—a regulatory gene whose protein product binds to Cdk complexes required for entry into and progress through S-phase. By blocking the kinase activity of these Cdk complexes, the p21 protein prevents the cell from entering S phase and replicating its DNA.

Cells defective in *p53* fail to show these responses. They tend to escape apoptosis, and if their DNA is damaged—by radiation or by some other mishap—they carry on dividing, plunging into DNA replication without pausing to repair the breaks and other DNA lesions that the damage has caused. As a result, they may either die or, far worse, survive and proliferate with a corrupted genome. A common consequence is that chromosomes become fragmented and incorrectly rejoined, creating, through further rounds of cell division, an increasingly disrupted genome as explained in [Figure 23-33](#). Such chromosomal mayhem can lead to both loss of tumor suppressor genes and activation of oncogenes, for example by gene amplification. In addition to being an important mechanism for activating oncogenes, gene amplification can also enable cells to develop resistance to therapeutic drugs, as we see below.

In summary, p53 helps a multicellular organism to cope safely with DNA damage and other stressful cellular events, acting as a check on cell proliferation in circumstances where it would be dangerous. Many cancer cells contain large quantities of mutant p53 protein (of an ineffectual variety), suggesting that the genetic accidents they undergo, or the stresses of growth in an inappropriate environment, have created the signals that normally call the p53 protein into play. The loss of *p53* activity can thus be treble dangerous in relation to cancer. First, it allows faulty mutant cells to continue through the

cell cycle. Second, it allows them to escape apoptosis. Third, it leads to the genetic instability characteristic of cancer cells, allowing further cancer-promoting mutations to accumulate as they divide. Many other mutations can contribute to each of these types of misbehavior, but p53 mutations contribute to them all. [↑ TOP](#)

DNA Tumor Viruses Activate the Cell's Replication Machinery by Blocking the Action of Key Tumor Suppressor Genes

DNA tumor viruses cause cancer mainly by interfering with cell-cycle controls, including those that depend on p53. To understand this type of viral carcinogenesis, it is important to understand the life history of the virus. Viruses use the DNA replication machinery of the host cell to replicate their own genomes. To make many infectious virus particles from a single host cell, a DNA virus has to commandeer this machinery and drive it hard, breaking through the normal constraints on DNA replication and usually killing the host cell in the process. Typically, however, the virus also has another option: it can propagate its genome as a quiet, well-behaved passenger in the host cell, replicating in parallel with the host cell's DNA in the course of ordinary cell division cycles. The virus can switch between these two modes of existence, remaining latent and harmless or proliferating to generate infectious particles according to circumstances. No matter which way of life the virus is following, it is not in its interests to cause cancer. But genetic accidents can occur, such that the virus misuses its equipment for commandeering the DNA replication machinery, and instead of switching on rapid replication of its own genome, switches on persistent proliferation of the host cell.

DNA viruses are a diverse group, but something of this sort seems to happen with most of those that are involved in cancer. The *papillomaviruses*, for example, are the cause of human warts and are especially important as a key causative factor in carcinomas of the uterine cervix (about 6% of all human cancers). Papillomaviruses infect the epithelium, and are retained in the basal layer of cells as extrachromosomal plasmids that replicate in step with the chromosomes. Infectious virus particles are generated in the outer epithelial layers, as cells begin to differentiate before being sloughed from the surface. Here, cell division should normally be arrested, but the virus interferes with this arrest so as to allow rapid replication of its own genome. Usually, the effect is restricted to the outer layers of cells and relatively harmless, as in a wart. Occasionally, through a genetic accident causing misregulation of the viral genes whose products prevent cell-cycle arrest, the control of cell division is subverted in the basal layer also, in the stem cells of the epithelium. This can lead to cancer, with the viral genes acting as oncogenes ([Figure 23-34](#)).

In papillomaviruses, the viral genes that are mainly to blame are called *E6* and *E7*. The products of these viral oncogenes interact with many host cell

proteins, but in particular they bind to the protein products of two key tumor suppressor genes of the host cell, putting them out of action and so permitting the cell to replicate its DNA and divide in an uncontrolled way. One of these host proteins is Rb: by binding to Rb, the viral E7 protein prevents it from binding to its normal associates in the cell. The other host protein inactivated by the virus is the tumor suppressor p53, which is bound by the viral E6 protein, triggering p53 destruction ([Figure 23-35](#)). Elimination of p53 allows the abnormal cell to survive, divide, and accumulate yet more abnormalities. [↑ TOP](#)

Telomere Shortening May Pave the Way to Cancer in Humans

The mouse is the most widely used model organism for the study of cancer, yet the spectrum of cancers seen in mice differs dramatically from that seen in humans. The great majority of mouse cancers are sarcomas and leukemias, whereas more than 80 percent of human cancers are carcinomas—cancers of epithelia where rapid cell turnover occurs (see [Figure 23-2](#)). Many therapies have been found to cure cancers in mice; but when the same treatments are tried in humans, they usually fail. What could be the reason for the difference between mouse and human cancer, and what can it tell us about the molecular mechanisms of the disease? An important part of the answer may lie in the behavior of telomeres and the relationship between telomere shortening, replicative cell senescence, and genetic instability.

As we saw earlier, most human cells seem to have a built-in limit to their proliferation: they show replicative senescence, at least when grown in culture. Replicative cell senescence in humans is thought to be caused by changes in the structure of telomeres—the repetitive DNA sequences and associated proteins that cap the ends of each chromosome. These telomeric DNA sequences are synthesized and maintained by a special mechanism that requires the enzyme telomerase, as explained in [Chapter 5](#). In most human cells, other than those of the germ line and some stem cells, expression of the gene coding for the catalytic subunit of telomerase is switched off, or at least not fully activated. As a result, the telomeres in these cells tend to become a little shorter with each round of cell division. Eventually, the telomeric cap on the chromosome end can become shortened to the point where a danger signal is generated, arresting the cell cycle. The signal is similar, in function at least, to the one that arrests the cycle when an uncapped DNA end is created by an accidental double-strand chromosome break. The effect in both cases is to prevent cell division so long as the cell contains broken or inadequately capped DNA. In the cell with the chromosome break, this allows time for DNA repair; in the normal senescent cell, it seems that it simply puts a stop to cell proliferation. As we discussed at the beginning of the chapter, it is not clear how often cells in normal human tissues run up against this limit; but if a self-renewing cell population does undergo replicative senescence, any rogue cell that undergoes a mutation that lets it carry on dividing will enjoy a huge

competitive advantage—much more than if the same mutation had occurred in a cell in a nonsenescent population. Viewed in this light, replicative senescence might be expected to favor the development of cancer.

Mice have telomeres much longer than those of humans. Moreover, unlike humans, they keep telomerase active in their somatic cells, and mouse telomeres therefore do not tend to shorten with increasing age of the organism. It is possible, however, to use gene knockout technology to make mice that lack functional telomerase. In these mice, the telomeres become shorter with every generation, but no untoward consequences are seen until, in the great-great-grandchildren of the initial mutants, the telomeres become so short that they disappear or cease to function. Beyond this point, the mice begin to show various abnormalities, including an increased incidence of cancer. This raises the possibility that natural telomere shortening helps to engender many human tumors. [↑ TOP](#)

In a Population of Telomere-Deficient Cells, Loss of p53 Opens an Easy Gateway to Cancer

In contrast with most normal cells in humans, most human cancer cells express telomerase. This is thought to be the reason why, unlike normal cells, they tend to divide without limit in culture, and it is added evidence that telomere maintenance has a significant role in cancer.

Given that cancer cells contain telomerase, an obvious suggestion is that they arise from mutant precursors that have simply avoided shortening their telomeres, and so have never encountered the telomeric limit to cell division. There is, however, another possibility, highlighted by the observations in the telomerase-deficient mice. A cancer may derive from a cell that has experienced telomere shortening, but has suffered a mutation that lets it disregard the signals that normally arrest cell division when telomeres are too short. A mutation causing loss of p53 activity can have just this effect: occurring in one cell within a population arrested by telomere shortening, it can give that cell and its progeny an immediate competitive advantage over their nondividing neighbors. At the same time, as explained in [Figure 23-36](#), the absence of p53 can bring on the gross chromosomal instability that is characteristic of human carcinomas, allowing the mutant cells to accumulate more mutations and evolve rapidly toward cancer. This is what appears to happen in the telomerase-deficient mice. If they lack not only telomerase but also one of their two copies of the *p53* gene, carcinomas become even more frequent. It is striking that these additional cancers are predominantly carcinomas—cancers of self-renewing epithelia—rather than the sarcomas and lymphomas usually seen in mice. Carcinomas constitute by far the commonest class of human tumors. The differences in telomere behavior could thereby account for the major difference observed between normal mice and humans in the predominant types of cancers that arise. Like human carcinoma cells, the mouse tumor cells are usually found to have inactivated their last

remaining *p53* gene; they also show gross chromosomal abnormalities, with many breaks, fusions, and broken chromosome ends.

If this scenario applies to cancers in humans, the suggestion would be that telomerase becomes reactivated after, not before, the genetic catastrophe. The progressive genetic disruption following loss of *p53* may be so severe that cells can rarely survive it for more than a few generations. A cell that reactivates telomerase expression will be able to halt the catastrophic cycle and regain enough chromosomal stability to survive (see [Figure 23-36](#)). Its progeny will inherit a highly abnormal chromosome set, with many mutations and alterations; these damaged cells can then continue to accumulate further mutations at a more moderate rate, driving tumor progression. This model tallies with the findings that, in breast and colorectal cancers, gross chromosomal abnormalities appear to arise early during tumor development, before telomerase is reactivated. With telomerase turned on, these carcinomas still possess enough genetic instability—due to a loss of *p53* or other mutations—to continue to evolve, thereby tending to become metastatic.

It is possible that many of the most common types of human carcinomas originate in the way we have just described. But there are certainly many other ways in which cancers can arise, and the true importance of replicative senescence and telomere behavior in human cancer remains to be determined. The uncertainties highlight how little we still know about the natural history of cancer, despite the dramatic advances in understanding of cancer molecular genetics. At the very least, however, the results suggest that telomere-deficient mice can provide a reasonable model for the study of common human carcinomas. Perhaps, this mouse model will also help us to devise cancer treatments that work as well in humans as they do in mice. [↑ TOP](#)

The Mutations That Lead to Metastasis Are Still a Mystery

Perhaps the most serious gap in our understanding of cancer concerns malignancy and metastasis. We have yet to clearly identify mutations that specifically permit cells to invade surrounding tissues, spread through the body, and form metastases. Indeed, it is not even clear exactly what properties a cancer cell must acquire to become metastatic. One extreme view would be that the ability of cancer cells in the body to metastasize requires no further genetic changes beyond those needed for loss of cell division control. An opposite view, more commonly espoused, is that metastasis is a difficult and complex task for a cell, requiring a mass of new mutations—so many, and so varied according to circumstance, that it is hard to discover what they are individually.

Which steps in metastasis are the most difficult is still a matter of debate. But there are experimental findings that throw some light on the issue. It is obvious, first of all, that metastasis presents different problems for different types of cells. For a leukemia cell, already roaming the body via the circulation, metastasis should be easier than for a carcinoma cell that has to

escape from an epithelium. As we saw at the beginning of the chapter, it is helpful to distinguish two degrees of malignancy for carcinomas, representing two phases of tumor progression. In the first phase, the tumor cells escape the normal confines of their parent epithelium and begin to invade the tissue immediately beneath—becoming *locally invasive*. In the second phase, they travel to distant sites and settle to form colonies, a process known as *metastasis*.

Local invasiveness requires a breakdown of the mechanisms that normally hold epithelial cells together. In some carcinomas of the stomach and of the breast, the *E-cadherin* gene has been identified as a tumor suppressor gene. The primary function of the E-cadherin protein is in cell-cell adhesion, where this protein is embedded in two adjacent plasma membranes to bind epithelial cells together (see [Figure 19-24](#)). When tumor cells lacking this adhesion molecule are placed in culture, and a functional *E-cadherin* gene is put back into them, they lose some of their invasive characteristics and begin to cohere more like normal cells. Loss of *E-cadherin*, therefore, may favor cancer by specifically contributing to local invasiveness.

The second stage of malignancy, involving entry into the bloodstream or lymphatic vessels, travel via the circulation, and colonization of remote sites, is more enigmatic. The cells must, for example, cross barriers such as the basal lamina of the parent epithelium and of blood vessels. Do they need to acquire additional mutations to become able to do this? The answer is not clear. To discover what steps in metastasis present cells with the greatest difficulties—and thus might be aided by the acquisition of additional mutations—one can label cancer cells with a fluorescent dye, inject them into the circulation of a living animal, and monitor their fate. In these experiments, many cells are found to survive in the circulation, to become lodged in small vessels, and to get out of these into the surrounding tissue, regardless of whether they come from a metastatic or a nonmetastatic tumor. Most of the losses occur after this. Some cells die immediately; others survive entry into the foreign tissue but fail to grow; still others divide a few times and then stop. Here the metastasis-competent cells outperform their nonmetastatic relatives, suggesting that the ability to grow in the foreign tissue is a key property that cells must acquire to become metastatic ([Figure 23-37](#)).

To discover the changes that confer metastatic potential, one can use DNA microarrays to look for genes that are selectively switched on in cancer cells that have become highly malignant. These microarrays allow one to monitor the expression of thousands of genes at a time (see [Figure 8-64](#)). One such study took human and mouse melanoma cells that had been selected for high metastatic potential and compared them with their poorly metastatic counterparts. Of the dozen or so genes that appeared to be selectively active in the malignant cells, one that showed increased expression repeatedly in the metastatic cells was *RhoC*—a member of a family of genes known to regulate cell motility (discussed in [Chapter 16](#)). A greatly expanded use of such methods, made much more powerful with the availability of the human

genome sequence, should soon give us a clearer picture of the molecular changes that allow tumor cells to metastasize. [↑ TOP](#)

Colorectal Cancers Evolve Slowly Via a Succession of Visible Changes

At the beginning of this chapter, we saw that most cancers develop gradually from a single aberrant cell, progressing from benign to malignant tumors by the accumulation of a number of independent genetic accidents. We have discussed what some of these accidents are in molecular terms and seen how they contribute to cancerous behavior. We now examine one particular class of common human cancers more closely, using it to illustrate and enlarge upon some of the general principles and molecular mechanisms we have introduced, and to see how we can make sense of the natural history of the disease in terms of them. We take **colorectal cancer** as our example, where the steps of tumor progression have been followed *in vivo* and carefully studied at the molecular level.

Colorectal cancers arise from the epithelium lining the colon and rectum (the lower end of the gut). They are common, currently causing over 60,000 deaths a year in the United States, or about 11% of total deaths from cancer. Like most cancers, they are not usually diagnosed until late in life (90% after the age of 55). However, routine examination of normal adults with a colonoscope (a fiber-optic device for viewing the interior of the colon and rectum) often reveals a small benign tumor, or adenoma, of the gut epithelium in the form of a protruding mass of tissue called a polyp ([Figure 23-38A](#)). These adenomatous polyps are believed to be the precursors of a large proportion of colorectal cancers. Because progression of the disease is usually very slow, there is typically a period of 10–35 years in which the slowly growing tumor is detectable but has not yet turned malignant. Thus, when people are screened by colonoscopy in their fifties and the polyps are removed—a quick and easy surgical procedure—the subsequent incidence of colorectal cancer is very low—according to some studies, less than a quarter of what it would be otherwise.

Colon cancer provides a clear example of the phenomenon of tumor progression discussed previously. In polyps smaller than 1 cm in diameter, the cells and the local details of their arrangement in the epithelium usually appear almost normal. The larger the polyp, the more likely it is to contain cells that look abnormally undifferentiated and form abnormally organized structures. Sometimes, two or more sectors can be distinguished within a single polyp, the cells in one sector appearing relatively normal, those in the other appearing frankly cancerous, as though they have arisen as a mutant subclone within the original clone of adenomatous cells. At later stages in the disease, the tumor cells become invasive, first breaking through the epithelial basal lamina, then spreading through the layer of muscle that surrounds the gut ([Figure 23-38B](#)), and finally metastasizing to lymph nodes, liver, lung, and other tissues. [↑ TOP](#)

A Few Key Genetic Lesions Are Common to a Majority of Cases of Colorectal Cancer

What are the mutations that accumulate with time to produce this chain of events? Of those genes so far discovered to be involved in colorectal cancer, three—*K-Ras* (a member of the *Ras* gene family), *p53*, and a third gene, *APC*, to be discussed below (Table 23-3)—stand out as very frequently mutated. Others are involved in smaller numbers of colon cancers. Still other critical genes remain to be identified.

One approach to discovery of the mutations responsible for colorectal cancer is to screen the cells for abnormalities in genes already known or suspected to be involved in cancers elsewhere. This type of genetic screening has revealed that about 40% of colorectal cancers have a specific point mutation in *K-Ras*, activating it as an oncogene, and about 60% have inactivating mutations or deletions of *p53*.

Another approach to finding cancer-critical genes is to track down the genetic defects in those rare families that show a hereditary predisposition to colorectal cancer. The first of these hereditary colorectal cancer syndromes to be elucidated was a condition known as *familial adenomatous polyposis coli* (*FAP*), in which hundreds or thousands of polyps develop along the length of the colon (Figure 23-39). These make their appearance in early adult life, and if they are not removed, it is almost inevitable that one or more of them will progress to become malignant; on average, 12 years elapse from the first detection of polyps to the diagnosis of cancer. The disease can be traced to deletion or inactivation of *APC*, a gene on the long arm of chromosome 5. Individuals with *FAP* have inactivating mutations or deletions of the *APC* gene in all the cells of the body. Of the patients with colorectal cancer who do not have the hereditary condition—the vast majority of cases of the disease—more than 60% have similar mutations in the cells of the cancer but not in their other tissues; in other words, both copies of the *APC* gene have been lost during their lifetime. Thus, by a route similar to that which we have discussed for retinoblastoma, mutation of *APC* is identified as one of the central ingredients of colorectal cancer.

As explained earlier, tumor suppressor genes can also be tracked down, even where there is no known hereditary syndrome, by searching for genetic deletions in the tumor cells. A systematic scan of a large number of colorectal cancers reveals frequent losses of large sections of certain chromosomes, suggesting that those regions may harbor tumor suppressor genes. One of them is the region including *APC*. Another includes the *SMAD4* gene, which is mutated in perhaps 30% of colon cancers. At least one other important tumor suppressor gene is thought to lie in the same neighborhood as *SMAD4* on chromosome 18 but remains to be identified. Specific parts of other chromosomes also show frequent losses—or gains—in colorectal cancers and are now being searched for additional cancer-critical genes.

As our knowledge of genes and their functions has expanded, another fruitful approach has been to look for genes that interact with a known cancer-critical gene in the hope that these, too, may be targets for mutation. The APC protein is now known to be an inhibitory component of the Wnt signaling pathway (discussed in [Chapter 15](#)). It acts by binding to β -catenin, another component of the pathway, and thereby preventing activation of TCF4, a gene regulatory protein that stimulates growth of the colonic epithelium when it has β -catenin bound to it. As we saw in [Chapter 22](#), loss of TCF4 causes a depletion of the gut stem-cell population, so that loss of the antagonist APC may cause overgrowth by the opposite effect. When the β -catenin gene was sequenced in a collection of colorectal tumors, it turned out that among the few that did not have APC mutations, a high proportion had activating mutations in β -catenin instead. Thus, it is the Wnt signaling pathway, rather than any single oncogene or tumor suppressor gene that it contains, that is critical for the cancer. [↑ TOP](#)

Defects in DNA Mismatch Repair Provide an Alternative Route to Colorectal Cancer

In addition to the hereditary disease associated with APC mutations, there is a second, and actually commoner, kind of hereditary predisposition to colon carcinoma in which the course of events is quite different from the one we have described for FAP. In patients with this condition, called *hereditary nonpolyposis colorectal cancer*, or *HNPCC*, the probability of colon cancer is increased without any increase in the number of colorectal polyps (adenomas). Moreover, the cancer cells in the tumors that develop are unusual, inasmuch as examination of their chromosomes in a microscope reveals a normal (or almost normal) karyotype and a normal (or almost normal) number of chromosomes. In contrast, the vast majority of colorectal tumors in non-HNPCC patients have gross chromosomal abnormalities, with multiple translocations, deletions, and other aberrations, and a total of 55 to 70 or more chromosomes instead of the normal 46 ([Figure 23-40](#)).

The mutations that predispose an individual with HNPCC to colorectal cancer turn out to be in one of several genes that code for central components of the DNA mismatch repair system in humans, homologous in structure and function to the *mutL* and *mutS* genes in bacteria and yeast (see [Figure 5-23](#)). Only one of the two copies of the involved gene is defective, so the inevitable DNA replication errors are efficiently removed in most of the patient's cells. However, as discussed previously for other tumor suppressor genes, these individuals are at risk, because the accidental loss or alteration of the remaining good gene copy will immediately elevate the spontaneous mutation rate by a hundred-fold or more (discussed in [Chapter 5](#)). These genetically unstable cells presumably go speeding through the standard processes of mutation and natural selection that allow clones of cells to progress to a malignancy.

This type of genetic instability produces invisible changes in the chromosomes—most notably changes in individual nucleotides and short expansions and contractions of mono- and dinucleotide repeats such as AAAA. . . or CACACA. . . . Once the phenomenon was recognized, mutations in mismatch repair genes were found in about 15% of the colorectal cancers occurring in normal people, with no inherited mutation. Again, the chromosomes in these cancers were unusual in having nearly normal karyotypes.

Thus genetic instability is found in practically all colorectal cancers, but it can be acquired in at least two very different ways. The majority of colorectal cancers have become unstable by rearranging their chromosomes—some perhaps as the combined result of a *p53* mutation and telomere shortening, as previously discussed. Others have been able to avoid this type of trauma; their genetic instability occurs on a much smaller scale, being caused by a defect in DNA mismatch repair. The fact that many carcinomas show either chromosomal instability or defective mismatch repair—but rarely both—clearly demonstrates that genetic instability is not an accidental byproduct of malignant behavior, but a contributory cause; it is a property that most cancer cells need in order to become malignant, but one that they can acquire in several alternative ways.  [TOP](#)

The Steps of Tumor Progression Can Be Correlated with Specific Mutations

In what sequence do *K-Ras*, *p53*, *APC*, and the other identified colorectal cancer genes undergo their mutations, and what contribution does each of them make to the eventual unruly behavior of the cancer cell? There cannot be a simple answer to this question, because colorectal cancer can arise by more than one route. Thus, as we have just seen, in some cases the first mutation leading toward the cancer may be in a DNA mismatch repair gene; in other cases, it may be in a gene regulating growth. A general feature, such as genetic instability, can arise in a variety of ways, through mutations in different genes.

Nevertheless, certain patterns of events are particularly common. Thus, mutations inactivating the *APC* gene appear to be the first, or at least a very early, step in most cases. They can be detected already in small benign polyps at the same high frequency as in large malignant tumors. Loss of *APC* seems to increase the rate of cell proliferation in the colonic epithelium relative to the rate of cell loss, without affecting the way the cells differentiate or the details of the histological pattern they form.

Mutations activating the *K-Ras* oncogene—a member of the *Ras* family—appear to take place a little later than those in *APC*; they are rare in small polyps but common in larger ones that show disturbances of cell differentiation and histological pattern. When malignant colorectal carcinoma cells containing such *Ras* mutations are grown in culture, they show typical

features of transformed cells, such as the ability to proliferate without anchorage to a substratum. Loss of cancer-critical genes on chromosome 18 and mutations in *p53* may come later still. They are rare in polyps but common in carcinomas, suggesting that they may often occur late in the sequence (Figure 23-41). As discussed earlier, loss of *p53* function is thought to allow the abnormal cells not only to avoid apoptosis and to divide, but also to accumulate additional mutations at a rapid rate by progressing through the cell cycle when they are not fit to do so, creating many abnormal chromosomes. [↑ TOP](#)

Each Case of Cancer Is Characterized by Its Own Array of Genetic Lesions

As we have just seen in colorectal cancer, the traditional classification of cancers is simplistic: a single one of the conventional categories of tumor will turn out—on close scrutiny—to be a heterogeneous collection of disorders with some features in common, but each characterized by its own array of genetic lesions (Figure 23-42). Many types of cancers that have been analyzed genetically show a large variety of genetic lesions and a great deal of variation from one case of the disease to another. In the form of lung cancer known as small-cell lung cancer, for example, one finds mutations not only in *Ras*, *p53*, and *APC*, but also in *Rb*, in members of the *Myc* gene family (in the form of amplification of the number of *Myc* gene copies), and in at least five other known proto-oncogenes and tumor suppressor genes. Different combinations of mutations are encountered in different patients and correspond to cancers that react differently to treatment.

In principle, molecular biology provides the tools to find out precisely which genes are amplified, which are deleted, and which are mutated in the tumor cells of any given patient. As we see in the next section, such information may soon prove to be as important for the diagnosis and treatment of cancer as is the identification of microorganisms in patients with infectious diseases. [↑ TOP](#)

Summary

Studies of developing embryos and transgenic mice have helped to reveal the functions of many cancer-critical genes. Most of the genes found to be mutated in cancer, both oncogenes and tumor suppressor genes, code for components of the pathways that regulate the social and proliferative behavior of cells in the body—in particular, the mechanisms by which signals from a cell's neighbors can impel it to divide, differentiate, or die. Other cancer-critical genes are involved in maintaining the integrity of the genome and guarding against damage. The molecular changes that allow cancers to metastasize, however, escaping the parent tumor and growing in foreign tissues, are still largely unknown.

DNA viruses such as papillomaviruses can promote the development of cancer

by sequestering the products of tumor suppressor genes—in particular, the Rb protein, which regulates cell division, and the p53 protein, which is thought to act as an emergency brake on cell division in cells that have suffered genetic damage and to call a halt to cell division in senescent cells with shortened telomeres.

The p53 protein has a dual role, regulating both progression through the cell cycle and the initiation of apoptosis. So loss or inactivation of p53, which occurs in about half of all human cancers, is doubly dangerous: it allows genetically damaged and senescent cells to continue to replicate their DNA, increasing the damage, and it allows them to escape apoptosis. The loss of p53 function may contribute to the genetic instability of many full-blown metastasizing cancers.

Generally speaking, the steps of tumor progression can be correlated with mutations that activate specific oncogenes and inactivate specific tumor suppressor genes. But different combinations of mutations are found in different forms of cancer and even in patients that nominally have the same form of the disease, reflecting the random way in which mutations occur. Nevertheless, many of the same types of genetic lesions are encountered repeatedly, suggesting that there is only a limited number of ways in which our defenses against cancer can be breached. Figure 23-30. Oncogene collaboration in transgenic mice. The graphs show the incidence of tumors in three types of transgenic mice, one carrying a *Myc* oncogene, one carrying a *Ras* oncogene, and one carrying both oncogenes. For these experiments two lines of transgenic mice were first constructed. One carries an inserted copy of an oncogene created by fusing the proto-oncogene *Myc* with the mouse mammary tumor virus regulatory DNA (which then drives *Myc* overexpression in specific tissues such as the mammary gland). The other line carries an inserted copy of the *Ras* oncogene under control of the same regulatory element. Both strains of mice develop tumors much more frequently than normal, most often in the mammary or salivary glands. Mice that carry both oncogenes together are obtained by crossing the two strains. These hybrids develop tumors at a far higher rate still, much greater than the sum of the rates for the two oncogenes separately. Nevertheless, the tumors arise only after a delay and only from a small proportion of the cells in the tissues where the two genes are expressed. Some further accidental change, in addition to the two oncogenes, is apparently required for the development of cancer. (After E. Sinn et al., *Cell* 49:465–475, 1987. © Elsevier.)

Figure 23-32. The pathway that controls cell cycling via Rb protein. All the components of this pathway have been found to be altered by mutation in human cancers (products of proto-oncogenes, *green*; products of tumor suppressor genes, *red*; E2F shown in *blue* because it has both inhibitory and stimulatory actions, depending on the other proteins that are bound to it). In most cases, only one of the components is altered in any individual tumor. (A) A simplified view of the dependency relationships in this pathway; see [Figure 17-30](#) for further details. (B) The Rb protein inhibits entry into the cell-division cycle when it is unphosphorylated. The complex of Cdk4 and cyclin D1 phosphorylates Rb, thereby encouraging cell proliferation. When a cell is stressed, p16 inhibits the formation of an active Cdk4/cyclin D1 complex, preventing proliferation. Inactivation of Rb or p16 by mutation encourages cell division (thus each can be regarded as a tumor suppressor) while overactivity of Cdk4 or cyclin D1 encourages cell division (thus each can be regarded as a proto-oncogene).

Figure 23-33. How the replication of damaged DNA can lead to chromosome abnormalities, gene amplification and gene loss. The diagram shows one of several possible mechanisms. The process begins with accidental DNA damage in a cell that lacks functional p53 protein. Instead of halting at the p53-dependent checkpoint in the division cycle, where a normal cell with damaged DNA would pause until the damage was repaired, the p53-defective cell enters S phase, with the consequences shown. Once a chromosome carrying a duplication and lacking a telomere has been generated, repeated rounds of replication, chromatid fusion, and unequal breakage (the so-called breakage-fusion-bridge cycle) can increase the number of copies of the duplicated region still further. Selection in favor of cells with increased numbers of copies of a gene in the affected chromosomal region will thus lead to mutants in which the gene is amplified to a high copy number. The multiple copies may eventually become visible as a homogeneously staining region in the chromosome, or they may—either through a recombination event or through unrepaired DNA strand breakage—become excised from their original locus and so appear as independent double minute chromosomes (see [Figure 23-28](#)). The chromosomal disorder can also lead to loss of genes, with selection in favor of cells that have lost tumor suppressors.

Figure 23-34. How certain papillomaviruses are thought to give rise to cancer of the uterine cervix. Papillomaviruses have double-stranded circular DNA chromosomes of about 8000 nucleotide pairs. In a wart or other benign infection these chromosomes are stably maintained in the basal cells of the epithelium as plasmids whose replication is regulated so as to keep step with the chromosomes of the host (*left*). Rare accidents can cause the integration of a fragment of such a plasmid into a chromosome of the host, altering the environment of the viral genes. This (or possibly some other cause) disrupts the control of viral gene expression. The unregulated production of viral replication proteins interferes with the control of cell division, thereby helping to generate a cancer (*right*).

Figure 23-35. Activation of cell proliferation by a DNA tumor virus.

Papillomavirus uses two viral proteins, E6 and E7, to sequester the host cell's p53 and Rb respectively. The SV40 virus (a related virus that infects monkeys) uses a single dual-purpose protein called large T antigen, for the same purpose. The E6 protein binding leads to ubiquitylation of its p53 partner, inducing p53 proteolysis (not shown).

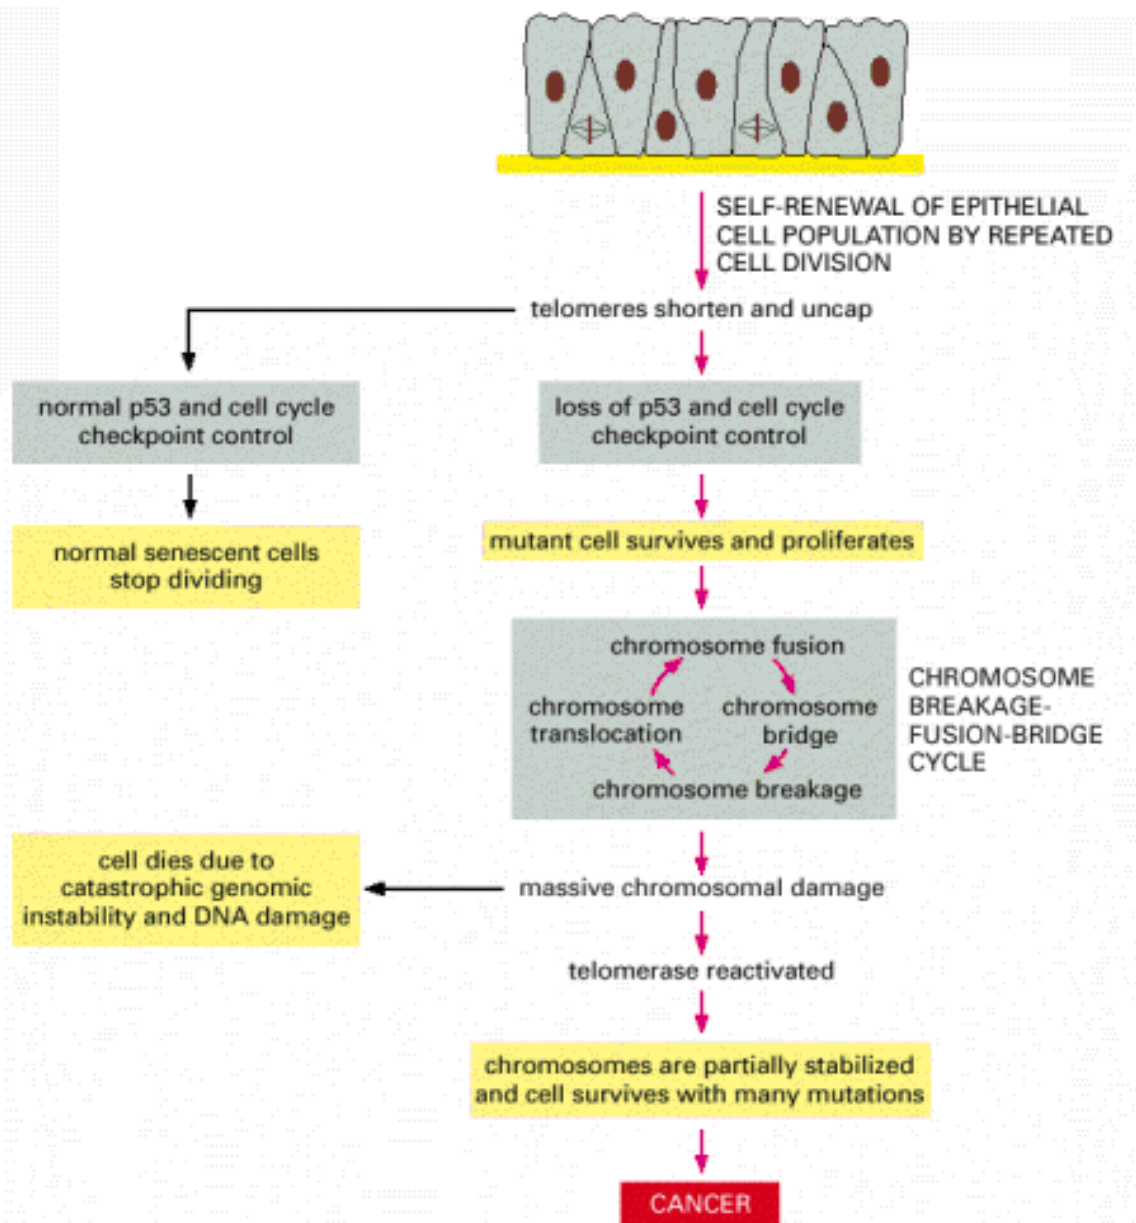

Figure 23-36. A view of how shortened telomeres may lead to chromosomal instability and cancer. Most human cells lack telomerase. As such cells divide, the telomeres that cap the ends of their chromosomes shrink. After many divisions, the telomeres become so short that they cease to function correctly, and the inadequately capped chromosome ends produce an intracellular signal similar to that produced by double-strand breaks. In the normal cells that still produce functional p53 and have their cell-cycle checkpoints intact, this triggers an arrest of cell division (replicative

senescence). But a rare cell within the cell population that has acquired a mutation in its p53 gene or in its cell-cycle checkpoints may ignore this signal and continue to divide, entering a breakage-fusion-bridge cycle that causes massive chromosomal damage (see [Figure 23-33](#)). Some cells may survive this period of genetic disruption by reactivating telomerase, which halts the catastrophic cycle and restores enough chromosomal stability for cell survival. These damaged cells can then go on to accumulate the additional mutations needed to produce a cancer.

Figure 23-37. The barriers to metastasis. Studies of labeled tumor cells leaving a tumor site, entering the circulation, and establishing metastases show which steps in the metastatic process, outlined in [Figure 23-15](#), are difficult or 'inefficient,' in the sense that they are steps in which large numbers of cells fail and are lost. It is in these difficult steps that highly metastatic cells are observed to have much greater success than nonmetastatic cells. It seems that the ability to escape from the parent tissue, and an ability to survive and grow in the foreign tissue, are key properties that cells must acquire to become metastatic. Figure 23-41. Suggested typical sequence of genetic changes underlying the development of a colorectal carcinoma. This over-simplified diagram provides a general idea of the way mutation and tumor development can fit together. But there are certainly other mutant genes of which we are not yet aware, and different colon cancers can progress through different sequences of mutations. There is still debate about the timing of p53 mutations and of the onset of genetic instability in relation to other mutations.

Cancer Treatment: Present and Future

How can we apply our growing understanding of the biology of cancer to combat the disease? Prevention is always better than cure, and as we have already discussed in the first part of this chapter, many cancers can indeed be prevented—first and foremost, by avoiding the use of tobacco, a more important hazard by far than any known carcinogen that is a by-product of our industrialized society. Moreover, cancers can often be nipped in the bud by screening: primary tumors can be detected early and removed before they have metastasized, as we saw for cervical cancers, for example. Many opportunities for better prevention and screening remain, some using highly sensitive new molecular assays. Advances in these areas probably offer the most immediate prospects of reducing the cancer death rate substantially. But prevention and screening can never be perfectly effective. It is certain that the full-blown malignant disease will continue to be common—and in need of treatment—for many years to come.

The Search for Cancer Cures Is Difficult but Not Hopeless

The difficulty of curing a cancer is similar to the difficulty of getting rid of weeds. Cancer cells can be removed surgically or destroyed with toxic chemicals or radiation; but it is hard to eradicate every single one of them. Surgery can rarely ferret out every metastasis, and treatments that kill cancer cells are generally toxic to normal cells as well. If even a few cancerous cells remain, they can proliferate to produce a resurgence of the disease; and, unlike the normal cells, they often evolve resistance to the poisons used against them. In spite of the difficulties, effective cures using anticancer drugs (alone or in combination with other treatments) have already been found for some formerly highly lethal cancers—notably Hodgkin's lymphoma, testicular cancer, choriocarcinoma, and some leukemias and other cancers of childhood. Even for types of cancer where a cure at present seems beyond our reach, there are treatments that will prolong life or at least relieve distress. But what prospect is there of doing better, and finding cures for the most common forms of cancer? [↑ TOP](#)

Current Therapies Exploit the Loss of Cell-Cycle Control and the Genetic Instability of Cancer Cells

Anticancer therapies need to take advantage of some property of cancer cells that distinguishes them from normal cells. One such property is the genetic instability that results from loss of chromosome maintenance or DNA repair mechanisms. Remarkably, it seems that most existing cancer therapies work because, unknown to the people who developed them, they exploit these molecular defects. Traditional anticancer therapies mostly rely on agents—drugs and ionizing radiation—that damage DNA and the machinery that maintains chromosomal integrity. Such treatments preferentially kill certain kinds of cancer cells because these mutants have a diminished ability to survive the damage. Normal cells, when treated with radiation, for example, will suffer damage to their DNA, but will then arrest their cell cycle until they have repaired it ([Figure 23-43](#)). Tumor cells that have defects in various cell-cycle checkpoints, on the other hand, lose the ability to arrest the cell cycle in these circumstances, and so continue to multiply immediately after irradiation. Almost all of these cells will therefore die after a few days as a result of the catastrophic DNA damage they sustain when they attempt to divide with defective chromosomes. [↑ TOP](#)

Cancers Can Evolve Resistance to Therapies

Unfortunately, while some of the molecular defects present in cancer cells may enhance their sensitivity to such cytotoxic agents, others may increase their resistance. For example, much of the cell death induced by DNA damage occurs through apoptosis, so cancer cells that harbor defects in their cell death programs can sometimes escape the effects of cytotoxic therapy. Cancer cells vary widely in their response to radiation and to the different kinds of cytotoxic drugs, and it seems likely that this difference reflects the particular kinds of defects they have in DNA repair, cell-cycle checkpoints, and apoptosis pathways.

Genetic instability itself can be both good and bad for anticancer therapy. Although it seems to provide an Achilles' heel that many conventional therapies exploit, genetic instability can also make eradicating cancer more difficult. Because of the abnormally high mutability of many cancer cells, most malignant tumor cell populations are heterogeneous in many respects, which may make them difficult to target with a single type of treatment. Moreover, this mutability allows many cancers to evolve resistance to therapeutic drugs at an alarming rate.

To make matters worse, cells that are exposed to one anticancer drug often develop a resistance not only to that drug, but also to other drugs to which they have never been exposed. This phenomenon of *multidrug resistance* is frequently correlated with amplification of a part of the genome that contains a gene called *Mdr1*. This gene codes for a plasma-membrane-bound transport ATPase (belonging to the ABC transporter superfamily discussed in [Chapter 11](#)). The overproduction of this protein or some other members of the same

family can prevent the intracellular accumulation of certain lipophilic drugs by pumping them out of the cell. The amplification of other types of genes can likewise give the cancer cell a selective advantage: thus the gene for the enzyme dihydrofolate reductase (DHFR) often becomes amplified in response to cancer chemotherapy with the folic-acid antagonist methotrexate. [↑ TOP](#)

New Therapies May Emerge From Our Knowledge of Cancer Biology

Our growing understanding of cancer cell biology and tumor progression is gradually leading to better methods for treating the disease, and not only by targeting defects in cell cycle arrest and DNA repair processes. As an example, estrogen antagonists (such as tamoxifen) and drugs that block estrogen synthesis are now widely used in patients to prevent or delay recurrence of breast cancer (and they are even being tested as agents to prevent new cancers from arising). Such antiestrogen compounds do not directly kill off the tumor cells. Nevertheless, they improve the patient's prospect of survival, presumably because estrogens are necessary for the growth of normal mammary epithelium and a proportion of breast cancers retain this hormone dependence.

The greatest hopes lie, however, in finding more powerful and selective ways to directly exterminate cancer cells. Now that we can pinpoint their genetic lesions, can we use our knowledge of cell biology to kill them off? In recent years, a wide variety of adventurous new ways to attack tumor cells have been suggested, many of which have been shown to work in model systems—typically reducing or preventing tumor growth in mice. Many of these protocols will turn out to be of no medical use, because they do not work in humans, have bad side effects, or are simply too difficult to implement. But some seem likely to succeed. For example, some tumor cells are heavily dependent on a particular protein that they overproduce (although it may not be unique to them). Blocking the activity of this protein may be an effective means of treating cancer if it does not unduly damage normal tissues. For example, about 25% of breast tumors express unusually high levels of the Her2 protein, a receptor tyrosine kinase, related to the EGF receptor, that normally plays a part in the development of the mammary epithelium. Thus, shutting off Her2 function might be expected to slow or halt the growth of breast tumors in humans; in fact, this approach is currently being tested with some success in clinical trials, using as the blocking agent a monoclonal antibody that recognizes Her2.

Another approach to destroying tumors targets the delivery of a toxic compound directly to the cancer cells by exploiting proteins like Her2 that are abundant on their surface. Antibodies against such proteins can be armed with a toxin, or made to carry an enzyme that cleaves a harmless 'prodrug' into a toxic molecule. In the latter case, one molecule of enzyme can then generate a large number of toxic molecules. A virtue of this strategy is that the toxic drug generated enzymatically can then diffuse to neighboring tumor cells,

increasing the odds that they too will be killed, even if the antibody did not bind to them directly. [↑ TOP](#)

Treatments Can Be Designed to Attack Cells That Lack p53

These treatments all target properties or molecules that tumor cells possess—but what about molecules that they lack? One ingenious way to target tumor cells exploits their loss of p53. Certain viruses, including the papillomaviruses and the adenoviruses, encode proteins that bind to and inactivate the host cell's p53 (see [Figure 23-35](#)). This enables these viruses to outwit the p53-mediated defenses of the host cell and replicate their own genomes freely inside it. As part of their lytic life style, adenoviruses replicate continuously inside an undefended cell, and then burst out when their numbers are sufficient, killing the cell and infecting its neighbors. An adenovirus has been constructed that lacks the gene that encodes the p53-blocking protein; this defective virus can therefore only replicate in cells in which p53 is already inactivated—including many types of cancer cells. If this modified adenovirus is injected into a tumor, the virus might be expected to replicate in and kill only the cancer cells that lack p53, leaving normal cells unharmed. This strategy is also undergoing clinical trials. [↑ TOP](#)

Tumor Growth Can Be Choked by Depriving the Cancer Cells of Their Blood Supply

Another promising approach to destroying tumors does not directly target cancer cells at all. Because tumors require the formation of new blood vessels to grow to more than a millimeter or so in size, treatments that block angiogenesis should block tumor growth in many different types of cancer. As discussed in [Chapter 22](#), growth of new vessels requires local signals—angiogenic growth factors—and the action of these molecules can, in principle, be blocked. Clinical trials with angiogenesis inhibitors are now taking place. Endothelial cells that are in the process of forming new vessels also turn out to express distinctive cell-surface markers, providing a promising way in which they might be attacked without harming the existing blood vessels in non-cancerous tissues. [↑ TOP](#)

Small Molecules Can Be Designed to Target Specific Oncogenic Proteins

The new treatments outlined above are still at an experimental stage. For most of them, it remains to be seen how effective they are in curing human cancers or in slowing their progress; past experience has taught us to be cautious. There is at least one recent dramatic success, however, that raises high hopes.

As we saw earlier, chronic myelogenous leukemia is associated, in more than 95% of cases, with a particular chromosomal translocation, visible as a

characteristic abnormality in the karyotype—the Philadelphia chromosome (see [Figure 23-5](#)). This is the consequence of chromosome breakage and rejoining at the sites of two specific genes, called *Abl* and *Bcr*. The fusion of these genes creates a hybrid gene that codes for a chimeric protein, consisting of the N-terminal fragment of Bcr fused to the C-terminal portion of Abl ([Figure 23-44](#)). Abl is a protein tyrosine kinase involved in cell signaling. The substitution of the Bcr fragment for its normal N terminus makes it hyperactive, so that it stimulates inappropriate proliferation of hemopoietic precursor cells that contain it and inhibits these cells from dying by apoptosis, which many of them would normally do. Excessive numbers of white blood cells are consequently made and released into the bloodstream, producing leukemia.

The chimeric Bcr-Abl protein is an obvious target for therapeutic attack. Searches for synthetic drug molecules that can inhibit the activity of protein kinases discovered one, called STI-571, that blocks Bcr-Abl ([Figure 23-45](#)). When this molecule, now renamed Gleevec, was given to a series of 54 patients with chronic myeloid leukemia that had resisted other treatments, all but one of them showed an excellent response, with return of their white blood cell counts to normal and, in some cases, an apparent eradication of the cells carrying the Philadelphia chromosome. After a year of treatment, 51 out of the initial 54 patients were still well. Results were not so good for patients who had already progressed through further mutations to the acute phase of myeloid leukemia, where genetic instability has set in and the march of the disease is far more rapid. These patients showed a response at first and then relapsed: the cancer cells were able to evolve a resistance to the Gleevec. Nevertheless, the extraordinary success of Gleevec for the patients in the chronic (early) stage of the disease is enough to prove the principle: once we understand precisely what genetic lesions have occurred in a cancer, we can begin to design effective rational methods to treat it. [↑ TOP](#)

Understanding of Cancer Biology Leads Toward Rational, Tailored Medical Treatments

All medical progress depends on accurate diagnosis. If one cannot identify a disease correctly, one cannot discover its causes, predict its outcome, select the appropriate treatment for a given patient, or conduct trials on a population of patients to judge whether a proposed treatment is effective. Cancers, as we have seen, are an extraordinarily heterogeneous collection of diseases. Nevertheless, new techniques provide tools to make diagnosis precise and specific. We have the means now to characterize each individual tumor at a molecular level in unprecedented detail. For example, by using DNA microarrays (as described in [Chapter 8](#)) to analyze the mRNA present in a tissue, the levels of expression of thousands of genes can be determined simultaneously in a single sample and compared with the levels in normal control tissue. Each case of a given form of cancer, such as breast cancer, has its own gene expression profile, but when the profiles of many patients are

compared it is found that they can be grouped into a smaller number of distinct classes whose members share common features. The different classes of gene expression profiles, reflecting the consequences of different sets of oncogenic mutations, correlate with different prognoses and different responses to therapy. These correlations are just beginning to be discovered, interpreted, and acted upon.

With our greatly increased understanding of molecular genetic mechanisms, we can for example, aim to determine for each tumor the precise defects in DNA metabolism—the alterations in DNA replication, DNA recombination, DNA repair, chromosome maintenance, and/or checkpoint controls—that have presumably in most cases helped its cells to acquire the multiple mutations required for tumor growth and invasiveness. These defects should make the tumor unusually vulnerable to particular types of attack on its DNA and its DNA-handling machinery. The observation that the cells of certain tumors are killed unusually easily by irradiation or by exposure to drugs that damage DNA supports this view. By designing precisely targeted drugs that exploit a particular weakness more precisely than these traditional treatments, we should be able to attack the cancer cells more effectively. In such ways, the molecular analysis of cancer promises to transform cancer treatment by enabling us to tailor therapy much more accurately to the individual patient.

The discovery of a range of cancer-critical genes has marked the end of an era of groping in the dark for clues to the molecular basis of cancer. It has been encouraging to find that there are, after all, some general principles and that some key genetic abnormalities are shared by many forms of the disease. But we are still far from fully understanding the most common human cancers. We know the DNA sequences of many cancer-critical genes, and the physiological functions of an increasing number of them. It is beginning to be possible to devise precisely targeted, rational treatments. But we still need a better understanding of how the relevant molecules interact to govern the behavior of the individual cell, a better understanding of the sociology of cells in tissues, and a better understanding of the many processes that govern the genesis and spread of cancer cells through mutation and natural selection.

Looking back on the history of cell biology and contemplating the speed of recent progress, we can be hopeful. The desire to understand that drives basic research will surely reveal new ways to use our knowledge of the cell for humanitarian goals, not only in relation to cancer, but also with regard to infectious disease, mental illness, agriculture, and other areas that we can scarcely foresee.  [TOP](#)

Summary

Our growing understanding of cancer cell biology should lead to better ways of diagnosing and treating this disease. Anticancer therapies can be designed to destroy cancer cells preferentially by exploiting the properties that distinguish them from normal cells, including the defects they harbor in their DNA repair

mechanisms, cell-cycle checkpoints, and apoptosis pathways. Tumors can also be attacked through their dependence on their blood supply. By understanding the normal control mechanisms and exactly how they are subverted in specific cancers, it becomes possible to devise drugs to target cancers more precisely. As we become better able to determine which genes are amplified, which are deleted, and which are mutated in the cells of any given tumor, we can begin to tailor treatments more accurately to each individual patient. Figure 23-43. Effects of ionizing radiation on normal cells (A) and cancer cells (B). Cancer cells tend to be more susceptible than normal cells to the damaging effects of ionizing radiation because they lack an ability to arrest the cell cycle and make the necessary repairs. Unfortunately, the same genetic defects may render some cancer cells resistant to radiation treatment, as they may also be less adept at activating apoptosis in the face of DNA damage.

Figure 23-44. The conversion of the *Abl* proto-oncogene into an oncogene in patients with chronic myelogenous leukemia. The chromosome translocation responsible joins the *Bcr* gene on chromosome 22 to the *Abl* gene from chromosome 9, thereby generating a Philadelphia chromosome (see [Figure 23-5](#)). The resulting fusion protein has the N-terminus of the Bcr protein joined to the C-terminus of the Abl tyrosine protein kinase; in consequence, the Abl kinase domain becomes inappropriately active, driving excessive proliferation of a clone of hemopoietic cells in the bone marrow.

24. The Adaptive Immune System

Our **adaptive immune system** saves us from certain death by infection. An infant born with a severely defective adaptive immune system will soon die unless extraordinary measures are taken to isolate it from a host of infectious agents, including bacteria, viruses, fungi, and parasites. Indeed, all multicellular organisms need to defend themselves against infection by such potentially harmful invaders, collectively called pathogens. Invertebrates use relatively simple defense strategies that rely chiefly on protective barriers, toxic molecules, and phagocytic cells that ingest and destroy invading microorganisms (*microbes*) and larger parasites (such as worms). Vertebrates, too, depend on such innate immune responses as a first line of defense (discussed in [Chapter 25](#)), but they can also mount much more sophisticated defenses, called adaptive immune responses. The innate responses call the adaptive immune responses into play, and both work together to eliminate the pathogens ([Figure 24-1](#)). Unlike innate immune responses, the adaptive responses are highly specific to the particular pathogen that induced them. They can also provide long-lasting protection. A person who recovers from measles, for example, is protected for life against measles by the adaptive immune system, although not against other common viruses, such as those that cause mumps or chickenpox. In this chapter, we focus mainly on adaptive immune responses, and, unless we indicate otherwise, the term immune responses refers to them. We discuss innate immune responses in detail in [Chapter 25](#).

The function of adaptive immune responses is to destroy invading pathogens and any toxic molecules they produce. Because these responses are destructive, it is crucial that they be made only in response to molecules that are foreign to the host and not to the molecules of the host itself. The ability to distinguish what is *foreign* from what is *self* in this way is a fundamental feature of the adaptive immune system. Occasionally, the system fails to make this distinction and reacts destructively against the host's own molecules. Such *autoimmune diseases* can be fatal.

Of course, many foreign molecules that enter the body are harmless, and it would be pointless and potentially dangerous to mount adaptive immune responses against them. Allergic conditions such as hayfever and asthma are

examples of deleterious adaptive immune responses against apparently harmless foreign molecules. Such inappropriate responses are normally avoided because the innate immune system calls adaptive immune responses into play only when it recognizes molecules characteristic of invading pathogens called **pathogen-associated immunostimulants** (discussed in [Chapter 25](#)). Moreover, the innate immune system can distinguish between different classes of pathogens and recruit the most effective form of adaptive immune response to eliminate them.

Any substance capable of eliciting an adaptive immune response is referred to as an antigen(*antibody generator*). Most of what we know about such responses has come from studies in which an experimenter tricks the adaptive immune system of a laboratory animal (usually a mouse) into responding to a harmless foreign molecule, such as a foreign protein. The trick involves injecting the harmless molecule together with immunostimulants (usually microbial in origin) called *adjuvants*, which activate the innate immune system. This process is called **immunization**. If administered in this way, almost any macromolecule, as long as it is foreign to the recipient, can induce an adaptive immune response that is specific to the administered macromolecule. Remarkably, the adaptive immune system can distinguish between antigens that are very similar—such as between two proteins that differ in only a single amino acid, or between two optical isomers of the same molecule.

Adaptive immune responses are carried out by white blood cells called lymphocytes. There are two broad classes of such responses—*antibody responses* and *cell-mediated immune responses*, and they are carried out by different classes of lymphocytes, called B cells and T cells, respectively. In **antibody responses**, B cells are activated to secrete antibodies, which are proteins called *immunoglobulins*. The antibodies circulate in the bloodstream and permeate the other body fluids, where they bind specifically to the foreign antigen that stimulated their production ([Figure 24-2](#)). Binding of antibody inactivates viruses and microbial toxins (such as tetanus toxin or diphtheria toxin) by blocking their ability to bind to receptors on host cells. Antibody binding also marks invading pathogens for destruction, mainly by making it easier for phagocytic cells of the innate immune system to ingest them.

In cell-mediated immune responses, the second class of adaptive immune response, activated T cells react directly against a foreign antigen that is presented to them on the surface of a host cell. The T cell, for example, might kill a virus-infected host cell that has viral antigens on its surface, thereby eliminating the infected cell before the virus has had a chance to replicate (see [Figure 24-2](#)). In other cases, the T cell produces signal molecules that activate macrophages to destroy the invading microbes that they have phagocytosed.

We begin this chapter by discussing the general properties of lymphocytes. We then consider the functional and structural features of antibodies that enable

them to recognize and neutralize extracellular microbes and the toxins they make. Next, we discuss how B cells can produce a virtually unlimited number of different antibody molecules. Finally, we consider the special features of T cells and the cell-mediated immune responses they are responsible for. Remarkably, T cells can detect microbes hiding inside host cells and either kill the infected cells or help other cells to eliminate the microbes. [↑ TOP](#)

Lymphocytes and the Cellular Basis of Adaptive Immunity

Lymphocytes are responsible for the astonishing specificity of adaptive immune responses. They occur in large numbers in the blood and lymph (the colorless fluid in the lymphatic vessels that connect the lymph nodes in the body to each other and to the bloodstream) and in lymphoid organs, such as the thymus, lymph nodes, spleen, and appendix ([Figure 24-3](#)).

In this section, we discuss the general properties of lymphocytes that apply to both B cells and T cells. We shall see that each lymphocyte is committed to respond to a specific antigen and that its response during its first encounter with an antigen ensures that a more rapid and effective response occurs on subsequent encounters with the same antigen. We consider how lymphocytes avoid responding to self antigens and how they continuously recirculate between the blood and lymphoid organs, ensuring that a lymphocyte will find its specific foreign antigen no matter where the antigen enters the body.

Lymphocytes Are Required for Adaptive Immunity

There are about 2×10^{12} lymphocytes in the human body, making the immune system comparable in cell mass to the liver or brain. Despite their abundance, their central role in adaptive immunity was not demonstrated until the late 1950s. The crucial experiments were performed in mice and rats that were heavily irradiated to kill most of their white blood cells, including lymphocytes. This treatment makes the animals unable to mount adaptive immune responses. Then, by transferring various types of cells into the animals it was possible to determine which cells reversed the deficiency. Only lymphocytes restored the adaptive immune responses of irradiated animals, indicating that lymphocytes are required for these responses ([Figure 24-4](#)). [↑ TOP](#)

The Innate and Adaptive Immune Systems Work Together

As mentioned earlier, lymphocytes usually respond to foreign antigens only if

the **innate immune system** is first activated. As discussed in [Chapter 25](#), the innate immune responses to an infection are rapid. They depend on *pattern recognition receptors* that recognize patterns of pathogen-associated molecules (immunostimulants) that are not present in the host organism, including microbial DNA, lipids, and polysaccharides, and proteins that form bacterial flagella. Some of these receptors are present on the surface of professional phagocytic cells such as macrophages and neutrophils, where they mediate the uptake of pathogens, which are then delivered to lysosomes for destruction. Others are secreted and bind to the surface of pathogens, marking them for destruction by either phagocytes or the complement system. Still others are present on the surface of various types of host cells and activate intracellular signaling pathways in response to the binding of pathogen-associated immunostimulants; this leads to the production of extracellular signal molecules that promote inflammation and help activate adaptive immune responses.

Some cells of the innate immune system directly present microbial antigens to T cells to initiate an adaptive immune response. The cells that do this most efficiently are called *dendritic cells*, which are present in most vertebrate tissues. They recognize and phagocytose invading microbes or their products at a site of infection and then migrate with their prey to a nearby peripheral lymphoid organ. There they act as *antigen-presenting cells*, which directly activate T cells to respond to the microbial antigens. Once activated, some of the T cells then migrate to the site of infection, where they help other phagocytic cells, mainly macrophages, destroy the microbes ([Figure 24-5](#)). Other activated T cells remain in the lymphoid organ and help B cells respond to the microbial antigens. The activated B cells secrete antibodies that circulate in the body and coat the microbes, targeting them for efficient phagocytosis.

Thus, innate immune responses are activated mainly at sites of infection, whereas adaptive immune responses are activated in peripheral lymphoid organs. The two types of responses work together to eliminate invading pathogens.  [TOP](#)

B Lymphocytes Develop in the Bone Marrow; T Lymphocytes Develop in the Thymus

T cells and B cells derive their names from the organs in which they develop. T cells develop in the *thymus*, and B cells, in mammals, develop in the *bone marrow* in adults or the liver in fetuses.

Despite their different origins, both T and B cells develop from the same *pluripotent hemopoietic stem cells*, which give rise to all of the blood cells, including red blood cells, white blood cells, and platelets. These stem cells (discussed in [Chapter 22](#)) are located primarily in *hemopoietic* tissues—mainly the liver in fetuses and the bone marrow in adults. T cells develop in the thymus from precursor cells that migrate there from the

hemopoietic tissues via the blood. In most mammals, including humans and mice, B cells develop from stem cells in the hemopoietic tissues themselves (Figure 24-6). Because they are sites where lymphocytes develop from precursor cells, the thymus and hemopoietic tissues are referred to as **central (primary) lymphoid organs** (see Figure 24-3).

As we discuss later, most lymphocytes die in the central lymphoid organ soon after they develop, without ever functioning. Others, however, mature and migrate via the blood to the **peripheral (secondary) lymphoid organs**—mainly, the lymph nodes, spleen, and epithelium-associated lymphoid tissues in the gastrointestinal tract, respiratory tract, and skin (see Figure 24-3). As mentioned earlier, it is in the peripheral lymphoid organs that T cells and B cells react with foreign antigens (see Figure 24-6).

T and B cells become morphologically distinguishable from each other only after they have been activated by antigen. Nonactivated T and B cells look very similar, even in an electron microscope. Both are small, only marginally bigger than red blood cells, and contain little cytoplasm (Figure 24-7A). Both are activated by antigen to proliferate and mature into *effector cells*. Effector B cells secrete antibodies. In their most mature form, called *plasma cells*, they are filled with an extensive rough endoplasmic reticulum (Figure 24-7B). In contrast, effector T cells (Figure 24-7C) contain very little endoplasmic reticulum and do not secrete antibodies.

There are two main classes of T cells—*cytotoxic T cells* and *helper T cells*. Cytotoxic T cells kill infected cells, whereas helper T cells help activate macrophages, B cells, and cytotoxic T cells. Effector helper T cells secrete a variety of signal proteins called cytokines, which act as local mediators. They also display a variety of costimulatory proteins on their surface. By means of these cytokines and membrane-bound costimulatory proteins, they can influence the behavior of the various cell types they help. Effector cytotoxic T cells kill infected target cells also by means of proteins that they either secrete or display on their surface. Thus, whereas B cells can act over long distances by secreting antibodies that are distributed by the bloodstream, T cells can migrate to distant sites, but there they act only locally on neighboring cells.  [TOP](#)

The Adaptive Immune System Works by Clonal Selection

The most remarkable feature of the adaptive immune system is that it can respond to millions of different foreign antigens in a highly specific way. B cells, for example, make antibodies that react specifically with the antigen that induced their production. How do B cells produce such a diversity of specific antibodies? The answer began to emerge in the 1950s with the formulation of the clonal selection theory. According to this theory, an animal first randomly generates a vast diversity of lymphocytes, and then those lymphocytes that can react against the foreign antigens that the animal actually encounters are

specifically selected for action. As each lymphocyte develops in a central lymphoid organ, it becomes committed to react with a particular antigen before ever being exposed to the antigen. It expresses this commitment in the form of cell-surface receptor proteins that specifically fit the antigen. When a lymphocyte encounters its antigen in a peripheral lymphoid organ, the binding of the antigen to the receptors activates the lymphocyte, causing it both to proliferate and to differentiate into an effector cell. An antigen therefore selectively stimulates those cells that express complementary antigen-specific receptors and are thus already committed to respond to it. This arrangement is what makes adaptive immune responses antigen-specific.

The term "clonal" in clonal selection theory derives from the postulate that the adaptive immune system is composed of millions of different families, or clones, of lymphocytes, each consisting of T or B cells descended from a common ancestor. Each ancestral cell was already committed to make one particular antigen-specific receptor protein, and so all cells in a clone have the same antigen specificity ([Figure 24-8](#)). According to the clonal selection theory, then, the immune system functions on the "ready-made" principle rather than the "made-to-order" one.

There is compelling evidence to support the main tenets of the clonal selection theory. For example, when lymphocytes from an animal that has not been immunized are incubated in a test tube with a number of radioactively labeled antigens, only a very small proportion (less than 0.01%) bind each antigen, suggesting that only a few cells are committed to respond to these antigens. Moreover, when one antigen is made so highly radioactive that it kills any cell that it binds to, the remaining lymphocytes can no longer produce an immune response to that particular antigen, even though they can still respond normally to other antigens. Thus, the committed lymphocytes must have receptors on their surface that specifically bind that antigen. Although most experiments of this kind have involved B cells and antibody responses, other experiments indicate that T cells, like B cells, operate by clonal selection.

How can the adaptive immune system produce lymphocytes that collectively display such an enormous diversity of receptors, including ones that recognize synthetic molecules that never occur in nature? We shall see later that the antigen-specific receptors on both T and B cells are encoded by genes that are assembled from a series of gene segments by a unique form of genetic recombination that occurs early in a lymphocyte's development, before it has encountered antigen. This assembly process generates the enormous diversity of receptors and lymphocytes, thereby enabling the immune system to respond to an almost unlimited diversity of antigens. [↑ TOP](#)

Most Antigens Activate Many Different Lymphocyte Clones

Most large molecules, including virtually all proteins and many polysaccharides, can serve as antigens. Those parts of an antigen that combine

with the antigen-binding site on either an antibody molecule or a lymphocyte receptor are called antigenic determinants (or *epitopes*). Most antigens have a variety of antigenic determinants that can stimulate the production of antibodies, specific T cell responses, or both. Some determinants of an antigen produce a greater response than others, so that the reaction to them may dominate the overall response. Such determinants are said to be *immunodominant*.

The diversity of lymphocytes is such that even a single antigenic determinant is likely to activate many clones, each of which produces an antigen-binding site with its own characteristic affinity for the determinant. Even a relatively simple structure, like the *dinitrophenyl (DNP)* group in [Figure 24-9](#), can be "looked at" in many ways. When it is coupled to a protein, as shown in the figure, it usually stimulates the production of hundreds of species of anti-DNP antibodies, each made by a different B cell clone. Such responses are said to be *polyclonal*. When only a few clones are activated, the response is said to be *oligoclonal*; and when the response involves only a single B or T cell clone, it is said to be *monoclonal*. Monoclonal antibodies are widely used as tools in biology and medicine, but they have to be produced in a special way (see [Figure 8-6](#)), as the responses to most antigens are polyclonal. [↑ TOP](#)

Immunological Memory Is Due to Both Clonal Expansion and Lymphocyte Differentiation

The adaptive immune system, like the nervous system, can remember prior experiences. This is why we develop lifelong immunity to many common infectious diseases after our initial exposure to the pathogen, and it is why vaccination works. The same phenomenon can be demonstrated in experimental animals. If an animal is immunized once with antigen A, an immune response (either antibody or cell-mediated) appears after several days, rises rapidly and exponentially, and then, more gradually, declines. This is the characteristic course of a primary immune response, occurring on an animal's first exposure to an antigen. If, after some weeks, months, or even years have elapsed, the animal is reinjected with antigen A, it will usually produce a secondary immune response that is very different from the primary response: the lag period is shorter, and the response is greater. These differences indicate that the animal has "remembered" its first exposure to antigen A. If the animal is given a different antigen (for example, antigen B) instead of a second injection of antigen A, the response is typical of a primary, and not a secondary, immune response. The secondary response must therefore reflect antigen-specific immunological memory for antigen A ([Figure 24-10](#)).

The clonal selection theory provides a useful conceptual framework for understanding the cellular basis of immunological memory. In an adult animal, the peripheral lymphoid organs contain a mixture of cells in at least three stages of maturation: *naïve cells*, *effector cells* and *memory cells*. When **naïve cells** encounter antigen for the first time, some of them are stimulated to

proliferate and differentiate into effector cells, which are actively engaged in making a response (effector B cells secrete antibody, while effector T cells kill infected cells or help other cells fight the infection). Instead of becoming effector cells, some naïve cells are stimulated to multiply and differentiate into **memory cells**—cells that are not themselves engaged in a response but are more easily and more quickly induced to become effector cells by a later encounter with the same antigen. Memory cells, like naïve cells, give rise to either effector cells or more memory cells (Figure 24-11).

Thus, immunological memory is generated during the primary response in part because the proliferation of antigen-stimulated naïve cells creates many memory cells—a process known as *clonal expansion*—and in part because memory cells are able to respond more sensitively and rapidly to the same antigen than do naïve cells. And, unlike most effector cells, which die within days or weeks, memory cells can live for the lifetime of the animal, thereby providing lifelong immunological memory. [↑ TOP](#)

Acquired Immunological Tolerance Ensures That Self Antigens Are Not Attacked

As discussed in Chapter 25, cells of the innate immune system recognize molecules on the surface of pathogens that are not found in the host. The adaptive immune system has a far more difficult recognition task: it must be able to respond specifically to an almost unlimited number of foreign macromolecules, while avoiding responding to the large number of molecules made by the host organism itself. How does it do it? For one thing, self molecules do not induce the innate immune reactions that are required to activate adaptive immune responses. But even when an infection triggers innate reactions, self molecules still do not normally induce adaptive immune responses. Why not?

One answer is that the adaptive immune system "learns" not to respond to self antigens. Transplantation experiments provide one line of evidence for this learning process. When tissues are transplanted from one individual to another, as long as the two individuals are not identical twins, the immune system of the recipient usually recognizes the donor cells as foreign and destroys them. (For reasons we discuss later, the foreign antigens on the donor cells are so powerful that they can stimulate adaptive immune responses in the absence of infection or an adjuvant.) If, however, cells from one strain of mouse are introduced into a neonatal mouse of another strain, some of these cells survive for most of the recipient animal's life, and the recipient will now accept a graft from the original donor, even though it rejects "third-party" grafts. Apparently, nonself antigens can, in some circumstances, induce the immune system to become specifically unresponsive to them. This antigen-specific unresponsiveness to foreign antigens is known as acquired immunological tolerance (Figure 24-12).

The unresponsiveness of an animal's adaptive immune system to its own macromolecules (*natural immunological tolerance*) is acquired in the same way. Normal mice, for example, cannot make an immune response against one of their own protein components of the complement system called C5 (discussed in [Chapter 25](#)). Mutant mice, however, that lack the gene encoding C5 (but are otherwise genetically identical to the normal mice) can make a strong immune response to this blood protein when immunized with it. Natural immunological tolerance for a particular self molecule persists only for as long as the molecule remains present in the body. If a self molecule such as C5 is removed, an animal gains the ability to respond to it after a few weeks or months. Thus, the immune system is genetically capable of responding to self molecules but learns not to do so.

The learning process that leads to self-tolerance can involve killing the self-reactive lymphocytes (*clonal deletion*), functionally inactivating them (*clonal anergy* or *inactivation*), stimulating the cells to produce modified receptors that no longer recognize the self antigen (*receptor editing*), or the suppression of self-reactive lymphocytes by a special type of regulatory T cell. The process begins in the central lymphoid organs when newly formed self-reactive lymphocytes first encounter their self antigen. Instead of being activated by binding antigen, the immature lymphocytes are induced to either alter their receptors or die by apoptosis. Lymphocytes that could potentially respond to self antigens that are not present in the central lymphoid organs often die or are either inactivated or suppressed after they have matured and migrated to peripheral lymphoid organs.

Why does the binding of self antigen lead to tolerance rather than activation? As we discuss later, for a lymphocyte to be activated in a peripheral lymphoid organ, it must not only bind its antigen but must also receive a *costimulatory signal*. The latter signal is provided by a helper T cell in the case of a B lymphocyte and by an antigen-presenting cell in the case of a T lymphocyte. The production of costimulatory signals usually depends on exposure to pathogens, and so a self-reactive lymphocyte normally encounters its antigen in the absence of such signals. Without a costimulatory signal, an antigen tends to kill or inactivate a lymphocyte rather than activate it ([Figure 24-13](#)).

Tolerance to self antigens sometimes breaks down, causing T or B cells (or both) to react against the organism's own tissue antigens. *Myasthenia gravis* is an example of such an [autoimmune disease](#). Affected individuals make antibodies against the acetylcholine receptors on their own skeletal muscle cells. These antibodies interfere with the normal functioning of the receptors so that the patients become weak and may die because they cannot breathe. The mechanisms responsible for the breakdown of tolerance to self antigens in autoimmune diseases are unknown. It is thought, however, that activation of the innate immune system by infection may help trigger certain anti-self responses in genetically susceptible individuals. [↑ TOP](#)

Lymphocytes Continuously Circulate Through Peripheral Lymphoid Organs

Pathogens generally enter the body through an epithelial surface, usually through the skin, gut, or respiratory tract. How do the microbial antigens travel from these entry points to a peripheral lymphoid organ, such as a lymph node or the spleen, where lymphocytes are activated (see [Figure 24-6](#))? The route and destination depend on the site of entry. Antigens that enter through the skin or respiratory tract are carried via the lymph to local lymph nodes; those that enter through the gut end up in gut-associated peripheral lymphoid organs such as Peyer's patches; and those that enter the blood are filtered out in the spleen. In most cases, dendritic cells carry the antigen from the site of infection to the peripheral lymphoid organ, where they become antigen-presenting cells (see [Figure 24-5](#)), specialized for activating T cells (as we discuss later).

But the lymphocytes that can recognize a particular microbial antigen in a peripheral lymph organ are only a tiny fraction of the total lymphocyte population. How do these rare cells find an antigen-presenting cell displaying their antigen? The answer is that they continuously circulate between the lymph and blood until they encounter their antigen. In a lymph node, for example, lymphocytes continually leave the bloodstream by squeezing out between specialized endothelial cells lining small veins called *postcapillary venules*. After percolating through the node, they accumulate in small lymphatic vessels that leave the node and connect with other lymphatic vessels that pass through other lymph nodes downstream (see [Figure 24-3](#)). Passing into larger and larger vessels, the lymphocytes eventually enter the main lymphatic vessel (the *thoracic duct*), which carries them back into the blood ([Figure 24-14](#)). This continuous recirculation between the blood and lymph ends only if a lymphocyte encounters its specific antigen (and a costimulatory signal) on the surface of an antigen-presenting cell in a peripheral lymphoid organ. Now the lymphocyte is retained in the peripheral lymphoid organ, where it proliferates and differentiates into effector cells. Some of the effector T cells then leave the organ via the lymph and migrate through the blood to the site of infection (see [Figure 24-5](#)).

Lymphocyte recirculation depends on specific interactions between the lymphocyte cell surface and the surface of the specialized endothelial cells lining the postcapillary venules in the peripheral lymphoid organs. Many cell types in the blood come into contact with these endothelial cells, but only lymphocytes adhere and then migrate out of the bloodstream. The lymphocytes initially adhere to the endothelial cells via *homing receptors* that bind to specific ligands (often called *counterreceptors*) on the endothelial cell surface. Lymphocyte migration into lymph nodes, for example, depends on a homing receptor protein called *L-selectin*, a member of the selectin family of cell-surface lectins discussed in [Chapter 19](#). This protein binds to specific sugar groups on a counterreceptor that is expressed exclusively on the surface of the specialized endothelial cells in lymph nodes, causing the lymphocytes to

adhere weakly to the endothelial cells and to roll slowly along their surface. The rolling continues until another, much stronger adhesion system is called into play by chemo-attractant proteins (called *chemokines*; see below) secreted by endothelial cells. This strong adhesion is mediated by members of the *integrin* family of cell adhesion molecules (discussed in [Chapter 19](#)), which become activated on the lymphocyte surface. Now the lymphocytes stop rolling and crawl out of the blood vessel into the lymph node ([Figure 24-15](#)).

Chemokines are small, secreted, positively charged proteins that have a central role in guiding the migrations of various types of white blood cells. They are all structurally related and bind to the surface of endothelial cells, and to negatively charged proteoglycans of the extracellular matrix in organs. By binding to G-protein-linked receptors (discussed in [Chapter 15](#)) on the surface of specific blood cells, chemokines attract these cells from the bloodstream into an organ, guide them to specific locations within the organ, and then help stop migration. (The AIDS virus (HIV) also binds to chemokine receptors, which allows the virus to infect white blood cells.) T and B cells initially enter the same region of a lymph node but are then attracted by different chemokines to separate regions of the node—T cells to the *paracortex* and B cells to *lymphoid follicles* ([Figure 24-16](#)). Unless they encounter their antigen, both types of cells soon leave the lymph node via lymphatic vessels. If they encounter their antigen, however, they remain in the node, proliferate, and differentiate into either effector cells or memory cells. Most of the effector cells leave the node, expressing different chemokine receptors that help guide them to their new destinations—T cells to sites of infection and B cells to the bone marrow. [↑ TOP](#)

Summary

Innate immune responses are triggered at sites of infection by microbe-specific molecules associated with invading pathogens. In addition to fighting infection directly, these responses help activate adaptive immune responses in peripheral lymphoid organs. Unlike innate immune responses, adaptive responses provide specific and long-lasting protection against the particular pathogen that induced them.

The adaptive immune system is composed of millions of lymphocyte clones, with the cells in each clone sharing a unique cell-surface receptor that enables them to bind a particular antigen. The binding of antigen to these receptors, however, is usually not sufficient to stimulate a lymphocyte to proliferate and differentiate into an effector cell that can help eliminate the pathogen. Costimulatory signals provided by another specialized cell in a peripheral lymphoid organ are also required. Helper T cells provide such signals for B cells, while antigen-presenting dendritic cells usually provide them for T cells. Effector B cells secrete antibodies, which can act over long distances to help eliminate extracellular pathogens and their toxins. Effector T cells, by contrast, act locally at sites of infection to either kill infected host cells or help other

cells to eliminate pathogens. As part of the adaptive immune response, some lymphocytes proliferate and differentiate into memory cells, which are able to respond faster and more efficiently the next time the same pathogen invades. Lymphocytes that would react against self molecules are either induced to alter their receptors, induced to kill themselves, inactivated, or suppressed, so that the adaptive immune system normally reacts only against foreign antigens. Both B and T cells circulate continuously between the blood and lymph. Only if they encounter their specific foreign antigen in a peripheral lymphoid organ do they stop migrating, proliferate, and differentiate into effector cells or memory cells. [↑ TOP](#)

Figure 24-4. A classic experiment showing that lymphocytes are required for adaptive immune responses to foreign antigens. An important requirement of all such cell-transfer experiments is that cells are transferred between animals of the same *inbred strain*. Members of an inbred strain are genetically identical. If lymphocytes are transferred to a genetically different animal that has been irradiated, they react against the "foreign" antigens of the host and can kill the animal. In the experiment shown, the injection of lymphocytes restores both antibody and cell-mediated adaptive immune responses, indicating that lymphocytes are required for both types of responses.

phagocytic cells of the innate immune system, including macrophages (not shown) and dendritic cells ingest invading microbes or their products at the site of infection. The dendritic cells then mature and migrate in lymphatic vessels to a nearby lymph node, where they serve as antigen-presenting cells. The antigen-presenting cells activate T cells to respond to the microbial antigens that are displayed on the presenting cells' surface. The antigen-presenting cells also have special proteins on their surface (called *costimulatory molecules*) that help activate the T cells. Some of the activated T cells then migrate to the site of infection where they either help activate macrophages or kill infected cells, thereby helping to eliminate the microbes. As we discuss later, the costimulatory molecules appear on dendritic cells only after these cells mature in response to invading microbes.

Figure 24-10. Primary and secondary antibody responses. The secondary response induced by a second exposure to antigen A is faster and greater than the primary response and is specific for A, indicating that the adaptive immune system has specifically remembered encountering antigen A before. The same type of immunological memory is observed in T-cell-mediated responses.

Figure 24-11. A model for the cellular basis of immunological memory.

When naïve lymphocytes are stimulated by their specific antigen, they proliferate and differentiate. Most become effector cells which function and then die, while others become long-lived memory cells. During a subsequent exposure to the same antigen, the memory cells respond more readily and rapidly than did the naïve cells: they proliferate and give rise to effector cells and to more memory cells. In the case of T cells, memory cells can also develop from effector cells (not shown).

Figure 24-12. Immunological tolerance. The skin graft seen here, transplanted from an adult brown mouse to an adult white mouse, has survived for many weeks only because the white mouse, at the time of its birth, received an injection of cells from the brown mouse and therefore became immunologically tolerant to them. The cells from the brown mouse persist in the adult white mouse and continue to induce tolerance in newly formed lymphocytes that would otherwise react against the brown skin. Figure 24-13. Induction of immunological tolerance to self antigens in central and peripheral lymphoid organs.

When a self-reactive immature lymphocyte binds its self antigen in the central lymphoid organ where the cell is produced, it may be induced to alter the receptor it makes so that it is no longer self-reactive. This process is called receptor editing and seems to occur only in developing B cells. Alternatively, the cell may die by apoptosis, a process called clonal deletion. When a self-reactive naïve lymphocyte escapes tolerance in the central lymphoid organ and binds its self antigen in a peripheral lymphoid organ, it may either die by apoptosis or be inactivated, as the binding usually occurs in the absence of a costimulatory signal. Although not shown, some self-reactive cells survive and are suppressed by special regulatory T cells. When a naïve lymphocyte binds a foreign antigen in a peripheral lymphoid organ in the presence of a costimulatory signal, it is stimulated to proliferate and differentiate into an effector or memory cell. As microbes are usually responsible for inducing costimulatory signals, most adaptive immune reactions normally occur only in response to microbes.

Figure 24-14. The path followed by lymphocytes as they continuously circulate between the lymph and blood. The circulation through a lymph node is shown here. Microbial antigens are carried into the lymph node by dendritic cells, which enter via afferent lymphatic vessels draining an infected tissue. T and B cells, by contrast, enter the lymph node via an artery and migrate out of the bloodstream through postcapillary venules. Unless they encounter their antigen, the T and B cells leave the lymph node via efferent lymphatic vessels, which eventually join the thoracic duct. The thoracic duct empties into a large vein carrying blood to the heart. A typical circulation cycle takes about 12–24 hours.

Figure 24-15. Migration of a lymphocyte out of the bloodstream into a lymph node. A circulating lymphocyte adheres weakly to the surface of the specialized endothelial cells lining a postcapillary venule in a lymph node. This initial adhesion is mediated by L-selectin on the lymphocyte surface. The adhesion is sufficiently weak to enable the lymphocyte to roll along the surface of the endothelial cells, pushed along by the flow of blood. Stimulated by chemokines secreted by the endothelial cells, the lymphocyte rapidly activates a stronger adhesion system, mediated by an integrin. This strong adhesion enables the cell to stop rolling and migrate out of the venule between the endothelial cells. The subsequent migration of the lymphocytes in the lymph node also depends on chemokines, which are produced within the node. The migration of other white blood cells out of the bloodstream into sites of infection occurs in a similar way.

Figure 24-16. A simplified drawing of a human lymph node. B cells are primarily clustered in structures called lymphoid follicles, whereas T cells are found mainly in the paracortex. Both types of lymphocytes are attracted by chemokines to enter the lymph node from the blood via postcapillary venules. They then migrate to their respective areas, attracted by different chemokines. If they do not encounter their specific antigen, both T cells and B cells then enter the medullary sinuses and leave the node via the efferent lymphatic vessel. This vessel ultimately empties into the bloodstream, allowing the lymphocytes to begin another cycle of circulation through a secondary lymphoid organ (see [Figure 24-14](#)).

B Cells and Antibodies

Vertebrates inevitably die of infection if they are unable to make antibodies. Antibodies defend us against infection by binding to viruses and microbial toxins, thereby inactivating them (see [Figure 24-2](#)). The binding of antibodies to invading pathogens also recruits various types of white blood cells and a system of blood proteins, collectively called *complement* (discussed in [Chapter 25](#)). The white blood cells and activated complement components work together to attack the invaders.

Synthesized exclusively by B cells, antibodies are produced in billions of forms, each with a different amino acid sequence and a different antigen-binding site. Collectively called *immunoglobulins* (abbreviated as **Ig**), they are among the most abundant protein components in the blood, constituting about 20% of the total protein in plasma by weight. Mammals make five classes of antibodies, each of which mediates a characteristic biological response following antigen binding. In this section, we discuss the structure and function of antibodies and how they interact with antigen.

B Cells Make Antibodies as Both Cell-Surface Receptors and Secreted Molecules

As predicted by the clonal selection theory, all antibody molecules made by an individual B cell have the same antigen-binding site. The first antibodies made by a newly formed B cell are not secreted. Instead, they are inserted into the plasma membrane, where they serve as receptors for antigen. Each B cell has approximately 10^5 such receptors in its plasma membrane. As we discuss later, each of these receptors is stably associated with a complex of transmembrane proteins that activate intracellular signaling pathways when antigen binds to the receptor.

Each B cell produces a single species of antibody, each with a unique antigen-binding site. When a naïve or memory B cell is activated by antigen (with the aid of a helper T cell), it proliferates and differentiates into an antibody-secreting effector cell. Such cells make and secrete large amounts of soluble

(rather than membrane-bound) antibody, which has the same unique antigen-binding site as the cell-surface antibody that served earlier as the antigen receptor ([Figure 24-17](#)). Effector B cells can begin secreting antibody while they are still small lymphocytes, but the end stage of their maturation pathway is a large *plasma cell* (see [Figure 24-7B](#)), which continuously secretes antibodies at the astonishing rate of about 2000 molecules per second. Plasma cells seem to have committed so much of their protein-synthesizing machinery to making antibody that they are incapable of further growth and division. Although many die after several days, some survive in the bone marrow for months or years and continue to secrete antibodies into the blood. [↑ TOP](#)

A Typical Antibody Has Two Identical Antigen-Binding Sites

The simplest antibodies are Y-shaped molecules with two identical antigen-binding sites, one at the tip of each arm of the Y ([Figure 24-18](#)). Because of their two antigen-binding sites, they are described as *bivalent*. As long as an antigen has three or more antigenic determinants, bivalent antibody molecules can cross-link it into a large lattice ([Figure 24-19](#)). This lattice can be rapidly phagocytosed and degraded by macrophages. The efficiency of antigen binding and cross-linking is greatly increased by a flexible *hinge region* in most antibodies, which allows the distance between the two antigen-binding sites to vary ([Figure 24-20](#)).

The protective effect of antibodies is not due simply to their ability to bind antigen. They engage in a variety of activities that are mediated by the tail of the Y-shaped molecule. As we discuss later, antibodies with the same antigen-binding sites can have any one of several different tail regions. Each type of tail region gives the antibody different functional properties, such as the ability to activate the complement system, to bind to phagocytic cells, or to cross the placenta from mother to fetus. [↑ TOP](#)

An Antibody Molecule Is Composed of Heavy and Light Chains

The basic structural unit of an antibody molecule consists of four polypeptide chains, two identical **light (L) chains** (each containing about 220 amino acids) and two identical **heavy (H) chains** (each usually containing about 440 amino acids). The four chains are held together by a combination of noncovalent and covalent (disulfide) bonds. The molecule is composed of two identical halves, each with the same antigen-binding site. Both light and heavy chains usually cooperate to form the antigen-binding surface ([Figure 24-21](#)). [↑ TOP](#)

There Are Five Classes of Heavy Chains, Each With Different Biological Properties

In mammals, there are five *classes* of antibodies, IgA, IgD, IgE, IgG, and IgM, each with its own class of heavy chain— α , δ , ϵ , γ , and μ , respectively. IgA molecules have α chains, IgG molecules have γ chains, and so on. In addition, there are a number of subclasses of IgG and IgA immunoglobulins; for example, there are four human IgG subclasses (IgG1, IgG2, IgG3, and IgG4), having γ_1 , γ_2 , γ_3 , and γ_4 heavy chains, respectively. The various heavy chains give a distinctive conformation to the hinge and tail regions of antibodies, so that each class (and subclass) has characteristic properties of its own.

IgM, which has μ heavy chains, is always the first class of antibody made by a developing B cell, although many B cells eventually switch to making other classes of antibody (discussed below). The immediate precursor of a B cell, called a *pre-B cell*, initially makes μ chains, which associate with so-called *surrogate light chains* (substituting for genuine light chains) and insert into the plasma membrane. The complexes of μ chains and surrogate light chains are required for the cell to progress to the next stage of development, where it makes bona fide light chains. The light chains combine with the μ chains, replacing the surrogate light chains, to form four-chain IgM molecules (each with two μ chains and two light chains). These molecules then insert into the plasma membrane, where they function as receptors for antigen. At this point, the cell is called an *immature naïve B cell*. After leaving the bone marrow, the cell starts to produce cell-surface **IgD** molecules as well, with the same antigen-binding site as the IgM molecules. It is now called a *mature naïve B cell*. It is this cell that can respond to foreign antigen in peripheral lymphoid organs ([Figure 24-22](#)).

IgM is not only the first class of antibody to appear on the surface of a developing B cell. It is also the major class secreted into the blood in the early stages of a *primary* antibody response, on first exposure to an antigen. (Unlike IgM, IgD molecules are secreted in only small amounts and seem to function mainly as cell-surface receptors for antigen.) In its secreted form, IgM is a pentamer composed of five four-chain units, giving it a total of 10 antigen-binding sites. Each pentamer contains one copy of another polypeptide chain, called a *J (joining) chain*. The J chain is produced by IgM-secreting cells and is covalently inserted between two adjacent tail regions ([Figure 24-23](#)).

The binding of an antigen to a single secreted pentameric IgM molecule can activate the complement system. As discussed in [Chapter 25](#), when the antigen is on the surface of an invading pathogen, this activation of complement can either mark the pathogen for phagocytosis or kill it directly.

The major class of immunoglobulin in the blood is **IgG**, which is a four-chain monomer produced in large quantities during *secondary* immune responses. Besides activating complement, the tail region of an IgG molecule binds to specific receptors on macrophages and neutrophils. Largely by means of such Fc receptors (so-named because antibody tails are called *Fc* regions), these

phagocytic cells bind, ingest, and destroy infecting microorganisms that have become coated with the IgG antibodies produced in response to the infection (Figure 24-24).

IgG molecules are the only antibodies that can pass from mother to fetus via the placenta. Cells of the placenta that are in contact with maternal blood have Fc receptors that bind blood-borne IgG molecules and direct their passage to the fetus. The antibody molecules bound to the receptors are first taken into the placental cells by receptor-mediated endocytosis. They are then transported across the cell in vesicles and released by exocytosis into the fetal blood (a process called *transcytosis*, discussed in Chapter 13). Because other classes of antibodies do not bind to these particular Fc receptors, they cannot pass across the placenta. IgG is also secreted into the mother's milk and is taken up from the gut of the neonate into the blood, providing protection for the baby against infection.

IgA is the principal class of antibody in secretions, including saliva, tears, milk, and respiratory and intestinal secretions. Whereas IgA is a four-chain monomer in the blood, it is an eight-chain dimer in secretions (Figure 24-25). It is transported through secretory epithelial cells from the extracellular fluid into the secreted fluid by another type of Fc receptor that is unique to secretory epithelia (Figure 24-26). This Fc receptor can also transport IgM into secretions (but less efficiently), which is probably why individuals with a selective IgA deficiency, the most common form of antibody deficiency, are only mildly affected by the defect.

The tail region of **IgE** molecules, which are four-chain monomers, binds with unusually high affinity ($K_a \sim 10^{10}$ liters/mole) to yet another class of Fc receptors. These receptors are located on the surface of *mast cells* in tissues and of *basophils* in the blood. The IgE molecules bound to them function as passively acquired receptors for antigen. Antigen binding triggers the mast cell or basophil to secrete a variety of cytokines and biologically active amines, especially *histamine* (Figure 24-27). These molecules cause blood vessels to dilate and become leaky, which in turn helps white blood cells, antibodies, and complement components to enter sites of infection. The same molecules are also largely responsible for the symptoms of such *allergic* reactions as hay fever, asthma, and hives. In addition, mast cells secrete factors that attract and activate white blood cells called *eosinophils*. These cells also have Fc receptors that bind IgE molecules and can kill various types of parasites, especially if the parasites are coated with IgE antibodies.

In addition to the five classes of heavy chains found in antibody molecules, higher vertebrates have two types of light chains, κ and λ , which seem to be functionally indistinguishable. Either type of light chain may be associated with any of the heavy chains. An individual antibody molecule, however, always contains identical light chains and identical heavy chains: an IgG molecule, for instance, may have either κ or λ light chains, but not one of each.

As a result of this symmetry, an antibody's antigen-binding sites are always identical. Such symmetry is crucial for the cross-linking function of secreted antibodies (see [Figure 24-19](#)).

The properties of the various classes of antibodies in humans are summarized in [Table 24-1](#).

The Strength of an Antibody-Antigen Interaction Depends on Both the Number and the Affinity of the Antigen-Binding Sites

The binding of an antigen to antibody, like the binding of a substrate to an enzyme, is reversible. It is mediated by the sum of many relatively weak non-covalent forces, including hydrogen bonds and hydrophobic van der Waals forces, and ionic interactions. These weak forces are effective only when the antigen molecule is close enough to allow some of its atoms to fit into complementary recesses on the surface of the antibody. The complementary regions of a four-chain antibody unit are its two identical antigen-binding sites; the corresponding region on the antigen is an *antigenic determinant* ([Figure 24-28](#)). Most antigenic macromolecules have many different antigenic determinants and are said to be *multivalent*; if two or more of them are identical (as in a polymer with a repeating structure), the antigen is said to be *polyvalent* ([Figure 24-29](#)).

The reversible binding reaction between an antigen with a single antigenic determinant (denoted Ag) and a single antigen-binding site (denoted Ab) can be expressed as

The equilibrium point depends both on the concentrations of Ab and Ag and on the strength of their interaction. Clearly, a larger fraction of Ab will become associated with Ag as the concentration of Ag increases. The strength of the interaction is generally expressed as the **affinity constant (K_a)** (see [Figure 3-44](#)), where

$$K_a = \frac{[\text{AgAb}]}{[\text{Ag}][\text{Ab}]}$$

(the square brackets indicate the concentration of each component at equilibrium).

The affinity constant, sometimes called the association constant, can be determined by measuring the concentration of free Ag required to fill half of the antigen-binding sites on the antibody. When half the sites are filled,

$[AgAb] = [Ab]$ and $K_a = 1/[Ag]$. Thus, the reciprocal of the antigen concentration that produces half the maximum binding is equal to the affinity constant of the antibody for the antigen. Common values range from as low as 5×10^4 to as high as 10^{11} liters/mole.

The **affinity** of an antibody for an antigenic determinant describes the strength of binding of a single copy of the antigenic determinant to a single antigen-binding site, and it is independent of the number of sites. When, however, a polyvalent antigen, carrying multiple copies of the same antigenic determinant, combines with a polyvalent antibody, the binding strength is greatly increased because all of the antigen-antibody bonds must be broken simultaneously before the antigen and antibody can dissociate. As a result, a typical IgG molecule can bind at least 100 times more strongly to a polyvalent antigen if both antigen-binding sites are engaged than if only one site is engaged. The total binding strength of a polyvalent antibody with a polyvalent antigen is referred to as the avidity of the interaction.

If the affinity of the antigen-binding sites in an IgG and an IgM molecule is the same, the IgM molecule (with 10 binding sites) will have a much greater avidity for a multivalent antigen than an IgG molecule (which has two binding sites). This difference in avidity, often 10^4 -fold or more, is important because antibodies produced early in an immune response usually have much lower affinities than those produced later. Because of its high total avidity, IgM—the major Ig class produced early in immune responses—can function effectively even when each of its binding sites has only a low affinity.

So far we have considered the general structure and function of antibodies. Next we look at the details of their structure, as revealed by studies of their amino acid sequence and three-dimensional structure. [↑ TOP](#)

Light and Heavy Chains Consist of Constant and Variable Regions

Comparison of the amino acid sequences of different antibody molecules reveals a striking feature with important genetic implications. Both light and heavy chains have a variable sequence at their N-terminal ends but a constant sequence at their C-terminal ends. Consequently, when the amino acid sequences of many different κ chains are compared, the C-terminal halves are the same or show only minor differences, whereas the N-terminal halves are all very different. Light chains have a **constant region** about 110 amino acids long and a variable region of the same size. The variable region of the heavy chains (at their N-terminus) is also about 110 amino acids long, but the heavy-chain constant region is about three or four times longer (330 or 440 amino acids), depending on the class (Figure 24-30).

It is the N-terminal ends of the light and heavy chains that come together to

form the antigen-binding site (see [Figure 24-21](#)), and the variability of their amino acid sequences provides the structural basis for the diversity of antigen-binding sites. The diversity in the variable regions of both light and heavy chains is for the most part restricted to three small hypervariable regions in each chain; the remaining parts of the variable region, known as *framework regions*, are relatively constant. Only the 5–10 amino acids in each hypervariable region form the antigen-binding site ([Figure 24-31](#)). As a result, the size of the antigenic determinant that an antibody recognizes is generally comparably small. It can consist of fewer than 25 amino acids on the surface of a globular protein, for example. [↑ TOP](#)

The Light and Heavy Chains Are Composed of Repeating Ig Domains

Both light and heavy chains are made up of repeating segments—each about 110 amino acids long and each containing one intrachain disulfide bond. These repeating segments fold independently to form compact functional units called **immunoglobulin (Ig) domains**. As shown in [Figure 24-32](#), a light chain consists of one variable (V_L) and one constant (C_L) domain (equivalent to the variable and constant regions shown in the top half of [Figure 24-30](#)). These domains pair with the variable (V_H) and first constant (C_{H1}) domain of the heavy chain to form the antigen-binding region. The remaining constant domains of the heavy chains form the F_c region, which determines the other biological properties of the antibody. Most heavy chains have three constant domains (C_{H1} , C_{H2} , and C_{H3}), but those of IgM and IgE antibodies have four.

The similarity in their domains suggests that antibody chains arose during evolution by a series of gene duplications, beginning with a primordial gene coding for a single 110 amino acid domain of unknown function. This hypothesis is supported by the finding that each domain of the constant region of a heavy chain is encoded by a separate coding sequence (exon) ([Figure 24-33](#)). [↑ TOP](#)

An Antigen-Binding Site Is Constructed From Hypervariable Loops

A number of fragments of antibodies, as well as intact antibody molecules, have been studied by x-ray crystallography. From these examples, we can understand the way in which billions of different antigen-binding sites are constructed on a common structural theme.

As illustrated in [Figure 24-34](#), each Ig domain has a very similar three-dimensional structure based on what is called the *immunoglobulin fold*, which consists of a sandwich of two β sheets held together by a disulfide bond. We

shall see later that many other proteins on the surface of lymphocytes and other cells, many of which function as cell-cell adhesion molecules (discussed in [Chapter 19](#)), contain similar domains and hence are members of a very large *immunoglobulin (Ig) superfamily* of proteins.

The variable domains of antibody molecules are unique in that each has its particular set of three hypervariable regions, which are arranged in three *hypervariable loops* (see [Figure 24-34](#)). The hypervariable loops of both the light and heavy variable domains are clustered together to form the antigen-binding site. Because the variable region of an antibody molecule consists of a highly conserved rigid framework, with hypervariable loops attached at one end, an enormous diversity of antigen-binding sites can be generated by changing only the lengths and amino acid sequences of the hypervariable loops. The overall three-dimensional structure necessary for antibody function remains constant.

X-ray analyses of crystals of antibody fragments bound to an antigenic determinant reveal exactly how the hypervariable loops of the light and heavy variable domains cooperate to form an antigen-binding surface in particular cases. The dimensions and shape of each different site vary depending on the conformations of the polypeptide chain in the hypervariable loops, which in turn are determined by the sequences of the amino acid side chains in the loops. The shapes of binding sites vary greatly—from pockets, to grooves, to undulating flatter surfaces, and even to protrusions—depending on the antibody ([Figure 24-35](#)). Smaller ligands tend to bind to deeper pockets, whereas larger ones tend to bind to flatter surfaces. In addition, the binding site can alter its shape after antigen binding to better fit the ligand.

Now that we have discussed the structure and functions of antibodies, we are ready to consider the crucial question that puzzled immunologists for many years—what are the genetic mechanisms that enable each of us to make many billions of different antibody molecules? [↑ TOP](#)

Summary

Antibodies defend vertebrates against infection by inactivating viruses and microbial toxins and by recruiting the complement system and various types of white blood cell to kill the invading pathogens. A typical antibody molecule is Y-shaped, with two identical antigen-binding sites at the tips of the Y and binding sites for complement components and/or various cell-surface receptors on the tail of the Y.

Each B cell clone makes antibody molecules with a unique antigen-binding site. Initially, during B cell development in the bone marrow, the antibody molecules are inserted into the plasma membrane, where they serve as receptors for antigen. In peripheral lymphoid organs, antigen binding to these receptors, together with costimulatory signals provided by helper T cells,

activates the B cells to proliferate and differentiate into either memory cells or antibody-secreting effector cells. The effector cells secrete antibodies with the same unique antigen-binding site as the membrane-bound antibodies.

A typical antibody molecule is composed of four polypeptide chains, two identical heavy chains and two identical light chains. Parts of both the heavy and light chains usually combine to form the antigen-binding sites. There are five classes of antibodies (IgA, IgD, IgE, IgG, and IgM), each with a distinctive heavy chain (α , δ , ϵ , γ , and μ , respectively). The heavy chains also form the tail (Fc region) of the antibody, which determines what other proteins will bind to the antibody and therefore what biological properties the antibody class has. Either type of light chain (κ or λ) can be associated with any class of heavy chain, but the type of light chain does not seem to influence the properties of the antibody, other than its specificity for antigen.

Each light and heavy chain is composed of a number of Ig domains— β sheet structures containing about 110 amino acids. A light chain has one variable (V_L) and one constant (C_L) domain, while a heavy chain has one variable (V_H) and three or four constant (C_H) domains. The amino acid sequence variation in the variable domains of both light and heavy chains is mainly confined to several small hypervariable regions, which protrude as loops at one end of the domains to form the antigen-binding site. Figure 24-17. B cell activation. When naïve or memory B cells are activated by antigen (and helper T cells — not shown), they proliferate and differentiate into effector cells. The effector cells produce and secrete antibodies with a unique antigen-binding site, which is the same as that of their original membrane-bound antibodies that served as antigen receptors.

Figure 24-19. Antibody-antigen interactions. Because antibodies have two identical antigen-binding sites, they can cross-link antigens. The types of antibody-antigen complexes that form depend on the number of antigenic determinants on the antigen. Here a single species of antibody (a monoclonal antibody) is shown binding to antigens containing one, two, or three copies of a single type of antigenic determinant. Antigens with two antigenic determinants can form small cyclic complexes or linear chains with antibody, while antigens with three or more antigenic determinants can form large three-dimensional lattices that readily precipitate out of solution. Most antigens have many different antigenic determinants (see [Figure 24-29A](#)), and different antibodies that recognize different determinants can cooperate in cross-linking the antigen (not shown).

Figure 24-21. A schematic drawing of a typical antibody molecule. It is composed of four polypeptide chains—two identical heavy chains and two identical light chains. The two antigen-binding sites are identical, each formed by the N-terminal region of a light chain and the N-terminal region of a heavy chain. Both the tail (Fc) and hinge region are formed by the two heavy chains.

Figure 24-23. A pentameric IgM molecule. The five subunits are held together by disulfide bonds (red). A single J chain, which has a structure similar to that of a single Ig domain (discussed later), is disulfide-bonded between the tails of two μ heavy chains. The J chain is required for pentamer formation. The addition of each successive four-chain IgM subunit requires a J chain, which is then discarded, except for the last one, which is retained. Note that IgM molecules do not have hinge regions.

Figure 24-26. The mechanism of transport of a dimeric IgA molecule across an epithelial cell. The IgA molecule, as a J-chain-containing dimer, binds to a transmembrane receptor protein on the nonluminal surface of a secretory epithelial cell. The receptor-IgA complexes are ingested by receptor-mediated endocytosis, transferred across the epithelial cell cytoplasm in vesicles, and secreted into the lumen on the opposite side of the cell by exocytosis. When exposed to the lumen, the part of the Fc receptor protein that is bound to the IgA dimer (the *secretory component*) is cleaved from its transmembrane tail, thereby releasing the antibody in the form shown in [Figure 24-25](#). The J chain is not shown.

Figure 24-27. The role of IgE in histamine secretion by mast cells. A mast cell (or a basophil) binds IgE molecules after they are secreted by activated B cells. The soluble IgE antibodies bind to Fc receptor proteins on the mast cell surface that specifically recognize the Fc region of these antibodies. The bound IgE molecules serve as cell-surface receptors for antigen. Thus, unlike B cells, each mast cell (and basophil) has a set of cell-surface antibodies with a wide variety of antigen-binding sites. When an antigen molecule binds to these membrane-bound IgE antibodies so as to cross-link them to their neighbors, it signals the mast cell to release its histamine and other local mediators by exocytosis.

Figure 24-28. Antigen binding to antibody. In this highly schematized diagram, an antigenic determinant on a macromolecule is shown interacting with the antigen-binding site of two different antibody molecules, one of high affinity and one of low affinity. The antigenic determinant is held in the binding site by various weak noncovalent forces, and the site with the better fit to the antigen has a greater affinity. Note that both the light and heavy chains of the antibody molecule usually contribute to the antigen-binding site.

Figure 24-32. Immunoglobulin domains. The light and heavy chains in an antibody molecule are each folded into repeating domains that are similar to one another. The variable domains (shaded in *blue*) of the light and heavy chains (V_L and V_H) make up the antigen-binding sites, while the constant domains of the heavy chains (mainly C_{H2} and C_{H3}) determine the other biological properties of the molecule. The heavy chains of IgM and IgE antibodies do not have a hinge region and have an extra constant domain (C_{H4}). Hydrophobic interactions between domains on adjacent chains have an important role in holding the chains together in the antibody molecule: V_L binds to V_H , C_L binds to C_{H1} , and so on (see [Figure 24-34](#)).

Molecular Biology of the Cell ➔ V. Cells in Their Social Context ➔ 24. The Adaptive Immune System

The Generation of Antibody Diversity

Even in the absence of antigen stimulation, a human can probably make more than 10^{12} different antibody molecules—its *preimmune antibody repertoire*. Moreover, the antigen-binding sites of many antibodies can cross-react with a variety of related but different antigenic determinants, making the antibody defense force even more formidable. The preimmune repertoire is apparently large enough to ensure that there will be an antigen-binding site to fit almost any potential antigenic determinant, albeit with low affinity. After repeated stimulation by antigen, B cells can make antibodies that bind their antigen with much higher affinity—a process called *affinity maturation*. Thus, antigen stimulation greatly increases the antibody arsenal.

Antibodies are proteins, and proteins are encoded by genes. Antibody diversity therefore poses a special genetic problem: how can an animal make more antibodies than there are genes in its genome? (The human genome, for example, contains fewer than 50,000 genes.) This problem is not quite as formidable as it might first appear. Recall that the variable regions of both the light and heavy chains of antibodies usually form the antigen-binding site. Thus, an animal with 1000 genes encoding light chains and 1000 genes encoding heavy chains could, in principle, combine their products in 1000×1000 different ways to make 10^6 different antigen-binding sites (although, in reality, not every light chain can combine with every heavy chain to make an antigen-binding site). Nonetheless, the mammalian immune system has evolved unique genetic mechanisms that enable it to generate an almost unlimited number of different light and heavy chains in a remarkably economical way, by joining separate *gene segments* together before they are transcribed. Birds and fish use very different strategies for diversifying antibodies, and even sheep and rabbits use somewhat different strategies from mice and humans. We shall confine our discussion to the mechanisms used by mice and humans.

We begin this section by discussing the mechanisms that B cells use to produce antibodies with an enormous diversity of antigen-binding sites. We then consider how a B cell can alter the tail region of the antibody it makes, while keeping the antigen-binding site unchanged. This ability allows the B cell to switch from making membrane-bound antibody to making secreted

 [Figure 24-41. An example of the DNA...](#)

antibody, or from making one class of antibody to making another, all without changing the antigen-specificity of the antibody.

Antibody Genes Are Assembled From Separate Gene Segments During B Cell Development

The first direct evidence that DNA is rearranged during B cell development came in the 1970s from experiments in which molecular biologists compared DNA from early mouse embryos, which do not make antibodies, with the DNA of a mouse B cell tumor, which makes a single species of antibody molecule. The specific variable (V)-region and constant (C)-region coding sequences that the tumor cells used were present on the same DNA restriction fragment in the tumor cells but on two different restriction fragments in the embryos. This showed that the DNA sequences encoding an antibody molecule are rearranged at some stage in B cell development ([Figure 24-36](#)).

We now know that each type of antibody chain— κ light chains, λ light chains, and heavy chains—has a separate pool of **gene segments** and exons from which a single polypeptide chain is eventually synthesized. Each pool is on a different chromosome and contains a large number of gene segments encoding the V region of an antibody chain and, as we saw in [Figure 24-33](#), a smaller number of exons encoding the C region. During the development of a B cell, a complete coding sequence for each of the two antibody chains to be synthesized is assembled by site-specific genetic recombination (discussed in [Chapter 5](#)). In addition to bringing together the separate gene segments and the C-region exons of the antibody gene, these rearrangements also activate transcription from the gene promoter through changes in the relative positions of the enhancers and silencers acting on the promoter. Thus, a complete antibody chain can be synthesized only after the DNA has been rearranged. As we shall see, the process of joining gene segments contributes to the diversity of antigen-binding sites in several ways. [↑ TOP](#)

Each Variable Region Is Encoded by More Than One Gene Segment

When genomic DNA sequences encoding V and C regions were first analyzed, it was found that a single region of DNA encodes the C region of an antibody chain (see [Figure 24-33](#)), but two or more regions of DNA have to be assembled to encode each V region. Each light-chain V region is encoded by a DNA sequence assembled from two gene segments—a long **Vgene segment** and a short *joining*, or **Jgene segment** (not to be confused with the protein *J chain* (see [Figure 24-23](#)), which is encoded elsewhere in the genome). [Figure 24-37](#) illustrates the genetic mechanisms involved in producing a human κ light-chain polypeptide from a C-region exon and separate V and J gene segments.

Each heavy-chain V region is encoded by a DNA sequence assembled from three gene segments—a *V* segment, a *J* segment, and a *diversity segment*, or **Dgene segment**. Figure 24-38 shows the number and organization of the gene segments used in making human heavy chains.

The large number of inherited *V*, *J*, and *D* gene segments available for encoding antibody chains makes a substantial contribution on its own to antibody diversity, but the combinatorial joining of these segments (called *combinatorial diversification*) greatly increases this contribution. Any of the 40 *V* segments in the human κ light-chain gene-segment pool, for example, can be joined to any of the 5 *J* segments (see Figure 24-37), so that at least 200 (40×5) different κ -chain V regions can be encoded by this pool. Similarly, any of the 51 *V* segments in the human heavy-chain pool can be joined to any of the 6 *J* segments and any of the 27 *D* segments to encode at least 8262 ($51 \times 6 \times 27$) different heavy-chain V regions.

The combinatorial diversification resulting from the assembly of different combinations of inherited *V*, *J*, and *D* gene segments just discussed is an important mechanism for diversifying the antigen-binding sites of antibodies. By this mechanism alone, a human can produce 287 different V_L regions (200 κ and 116 λ) and 8262 different V_H regions. In principle, these could then be combined to make about 2.6×10^6 (316×8262) different antigen-binding sites. In addition, as we discuss next, the joining mechanism itself greatly increases this number of possibilities (probably more than 10^8 -fold), making it much greater than the total number of B cells (about 10^{12}) in a human. [↑ TOP](#)

Imprecise Joining of Gene Segments Greatly Increases the Diversity of V Regions

During B cell development, the *V* and *J* gene segments (for the light chain) and the *V*, *D*, and *J* gene segments (for the heavy chain) are joined together to form a functional V_L - or V_H -region coding sequence by a process of site-specific recombination called **V(D)J joining**. Conserved DNA sequences flank each gene segment and serve as recognition sites for the joining process, ensuring that only appropriate gene segments recombine. Thus, for example, a *V* segment will always join to a *J* or *D* segment but not to another *V* segment. Joining is mediated by an enzyme complex called the **V(D)J recombinase**. This complex contains two proteins that are specific to developing lymphocytes, as well as enzymes that help repair damaged DNA in all our cells.

The lymphocyte-specific proteins of the V(D)J recombinase are encoded by two closely linked genes called *rag-1* and *rag-2* (*rag* = recombination activating genes). The **RAG proteins** introduce double-strand breaks at the flanking DNA sequences, and this is followed by a rejoining process that is

mediated by both the RAG proteins and the enzymes involved in general DNA double-strand repair (discussed in [Chapter 5](#)). Thus, if both *rag* genes are artificially expressed in a fibroblast, the fibroblast is now able to rearrange experimentally introduced antibody gene segments just as a developing B cell normally does. Moreover, individuals who are deficient in either *rag* gene or in one of the general repair enzymes are highly susceptible to infection because they are unable to carry out *V(D)J* joining and consequently do not have functional B or T cells. (T cells use the same recombinase to assemble the gene segments that encode their antigen-specific receptors.)

In most cases of site-specific recombination, DNA joining is precise. But during the joining of antibody (and T cell receptor) gene segments, a variable number of nucleotides are often lost from the ends of the recombining gene segments, and one or more randomly chosen nucleotides may also be inserted. This random loss and gain of nucleotides at joining sites is called **junctional diversification**, and it enormously increases the diversity of V-region coding sequences created by recombination, specifically in the third hypervariable region. This increased diversification comes at a price, however. In many cases, it will result in a shift in the reading frame that produces a nonfunctional gene. Because roughly two in every three rearrangements are "nonproductive" in this way, many developing B cells never make a functional antibody molecule and consequently die in the bone marrow. B cells making functional antibody molecules that bind strongly to self antigens in the bone marrow are stimulated to re-express the RAG proteins and undergo a second round of *V(D)J* rearrangements, thereby changing the specificity of the cell-surface antibody they make—a process referred to as **receptor editing**. Self-reactive B cells that fail to change their specificity in this way are eliminated through the process of clonal deletion (see [Figure 24-13](#)).  [TOP](#)

Antigen-Driven Somatic Hypermutation Fine-Tunes Antibody Responses

As mentioned earlier, with the passage of time after immunization, there is usually a progressive increase in the affinity of the antibodies produced against the immunizing antigen. This phenomenon, known as affinity maturation, is due to the accumulation of point mutations specifically in both heavy-chain and light-chain V-region coding sequences. The mutations occur long after the coding regions have been assembled, when B cells are stimulated by antigen and helper T cells to generate memory cells in a lymphoid follicle in a peripheral lymphoid organ (see [Figure 24-16](#)). They occur at the rate of about one per V-region coding sequence per cell generation. Because this is about a million times greater than the spontaneous mutation rate in other genes, the process is called **somatic hypermutation**. The molecular mechanism is still uncertain, but it is believed to involve some form of error-prone DNA repair process targeted to the rearranged V-region coding sequence by specific regions of DNA brought together by *V(D)J* joining. Surprisingly, an enzyme involved in RNA editing (discussed in [Chapter 7](#)) is required, but its function

in the hypermutation process is unknown.

Only a small minority of the altered antigen receptors generated by hypermutation have an increased affinity for the antigen. The few B cells expressing these higher-affinity receptors, however, are preferentially stimulated by the antigen to survive and proliferate, whereas most other B cells die by apoptosis. Thus, as a result of repeated cycles of somatic hypermutation, followed by antigen-driven proliferation of selected clones of memory B cells, antibodies of increasingly higher affinity become abundant during an immune response, providing progressively better protection against the pathogen.

The main mechanisms of antibody diversification are summarized in [Figure 24-39](#). [↑ TOP](#)

The Control of V(D)J Joining Ensures That B Cells Are Monospecific

As the clonal selection theory predicts, B cells are *monospecific*. That is, all the antibodies that any one B cell produces have identical antigen-binding sites. This property enables antibodies to cross-link antigens into large aggregates, thereby promoting antigen elimination (see [Figure 24-19](#)). It also means that an activated B cell secretes antibodies with the same specificity as that of the membrane-bound antibody on the B cell that was originally stimulated.

The requirement of monospecificity means that each B cell can make only one type of V_L region and one type of V_H region. Since B cells, like most other somatic cells, are diploid, each cell has six gene-segment pools encoding antibody chains: two heavy-chain pools (one from each parent) and four light-chain pools (one κ and one λ from each parent). If DNA rearrangements occurred independently in each heavy-chain pool and each light-chain pool, a single cell could make up to eight different antibodies, each with a different antigen-binding site.

In fact, however, each B cell uses only two of the six gene-segment pools: one of the two heavy-chain pools and one of the four light-chain pools. Thus, each B cell must choose not only between its κ and λ light-chain pools, but also between its maternal and paternal light-chain and heavy-chain pools. This second choice is called [allelic exclusion](#), and it also occurs in the expression of genes that encode T cell receptors. For most other proteins that are encoded by autosomal genes, both maternal and paternal genes in a cell are expressed about equally.

Allelic exclusion and κ versus λ light-chain choice during B cell development depend on negative feedback regulation of the V(D)J joining process. A functional rearrangement in one gene-segment pool suppresses rearrangements

in all remaining pools that encode the same type of polypeptide chain ([Figure 24-40](#)). In B cell clones isolated from transgenic mice expressing a rearranged μ -chain gene, for example, the rearrangement of endogenous heavy-chain genes is usually suppressed. Comparable results have been obtained for light chains. The suppression does not occur if the product of the rearranged gene fails to assemble into a receptor that inserts into the plasma membrane. It has therefore been proposed that either the receptor assembly process itself or extracellular signals that act on the receptor are involved in the suppression of further gene rearrangements.

Although no biological differences between the constant regions of κ and λ light chains have been discovered, there is an advantage in having two separate pools of gene segments encoding light chain variable regions. Having two separate pools increases the chance that a pre-B cell that has successfully assembled a V_H -region coding sequence will go on to assemble successfully a V_L -region coding sequence to become a B cell. This chance is further increased because, before a developing pre-B cell produces ordinary light chains, it makes surrogate light chains (see [Figure 24-22](#)), which assemble with μ heavy chains. The resulting receptors are displayed on the cell surface and allow the cell to proliferate, producing large numbers of progeny cells, some of which are likely to succeed in producing bona fide light chains. [↑ TOP](#)

When Activated by Antigen, a B Cell Switches From Making a Membrane-Bound Antibody to Making a Secreted Form of the Same Antibody

We now turn from the genetic mechanisms that determine the antigen-binding site of an antibody to those that determine its biological properties—that is, those that determine what form of heavy-chain constant region is synthesized. The choice of the particular gene segments that encode the antigen-binding site is a commitment for the life of a B cell and its progeny, but the type of C_H region that is made changes during B cell development. The changes are of two types: changes from a membrane-bound form to a secreted form of the same C_H region and changes in the class of the C_H region made.

All classes of antibody can be made in a membrane-bound form, as well as in a soluble, secreted form. The membrane-bound form serves as an antigen receptor on the B cell surface, while the soluble form is made only after the cell is activated by antigen to become an antibody-secreting effector cell (see [Figure 24-17](#)). The sole difference between the two forms resides in the C-terminus of the heavy chain. The heavy chains of membrane-bound antibody molecules have a hydrophobic C-terminus, which anchors them in the lipid bilayer of the B cell's plasma membrane. The heavy chains of secreted antibody molecules, by contrast, have instead a hydrophilic C-terminus, which allows them to escape from the cell. The switch in the character of the

antibody molecules made occurs because the activation of B cells by antigen (and helper T cells) induces a change in the way in which the H-chain RNA transcripts are made and processed in the nucleus (see [Figure 7-93](#)). [↑ TOP](#)

B Cells Can Switch the Class of Antibody They Make

During B cell development, many B cells switch from making one class of antibody to making another—a process called class switching. All B cells begin their antibody-synthesizing lives by making IgM molecules and inserting them into the plasma membrane as receptors for antigen. After the B cells leave the bone marrow, but before they interact with antigen, they switch and make both IgM and IgD molecules as membrane-bound antigen receptors, both with the same antigen-binding sites (see [Figure 24-22](#)). On stimulation by antigen and helper T cells, some of these cells are activated to secrete IgM antibodies, which dominate the primary antibody response. Later in the immune response, the combination of antigen and the cytokines that helper T cells secrete induce many B cells to switch to making IgG, IgE, or IgA antibodies. These cells generate both memory cells that express the corresponding classes of antibody molecules on their surface and effector cells that secrete the antibodies. The IgG, IgE, and IgA molecules are collectively referred to as *secondary* classes of antibodies, both because they are produced only after antigen stimulation and because they dominate secondary antibody responses. As we saw earlier, each different class of antibody is specialized to attack microbes in different ways and in different sites.

The constant region of an antibody heavy chain determines the class of the antibody. Thus, the ability of B cells to switch the class of antibody they make without changing the antigen-binding site implies that the same assembled V_H -region coding sequence (which specifies the antigen-binding part of the heavy chain) can sequentially associate with different C_H -coding sequences. This has important functional implications. It means that, in an individual animal, a particular antigen-binding site that has been selected by environmental antigens can be distributed among the various classes of antibodies, thereby acquiring the different biological properties of each class.

When a B cell switches from making IgM and IgD to one of the secondary classes of antibody, an irreversible change at the DNA level occurs—a process called *class switch recombination*. It entails deletion of all the C_H -coding sequences between the assembled VDJ-coding sequence and the particular C_H -coding sequence that the cell is destined to express ([Figure 24-41](#)). Switch recombination differs from $V(D)J$ joining in several ways: (1) it involves noncoding sequences only and therefore leaves the coding sequence unaffected; (2) it uses different flanking recombination sequences and different enzymes; (3) it happens after antigen stimulation; and (4) it is dependent on helper T cells. [↑ TOP](#)

Summary

Antibodies are produced from three pools of gene segments and exons. One pool encodes κ light chains, one encodes λ light chains, and one encodes heavy chains. In each pool, separate gene segments that code for different parts of the variable region of the light or heavy chains are brought together by site-specific recombination during B cell development. The light-chain pools contain one or more constant- (C-) region exons and sets of variable (V) and joining (J) gene segments. The heavy-chain pool contains sets of C-region exons and sets of V, diversity (D), and J gene segments.

To make an antibody molecule, a V_L gene segment recombines with a J_L gene segment to produce a DNA sequence coding for the V region of a light chain, and a V_H gene segment recombines with a D and a J_H gene segment to produce a DNA sequence coding for the V region of a heavy chain. Each of the assembled V-region coding sequences is then cotranscribed with the appropriate C-region sequence to produce an RNA molecule that codes for the complete polypeptide chain. Cells making functional heavy and light chains turn off the V(D)J joining process to ensure that each B cell makes only one species of antigen-binding site.

By randomly combining inherited gene segments that code for V_L and V_H regions, humans can make hundreds of different light chains and thousands of different heavy chains. Because the antigen-binding site is formed where the hypervariable loops of the V_L and V_H come together in the final antibody, the heavy and light chains can pair to form antibodies with millions of different antigen-binding sites. This number is enormously increased by the loss and gain of nucleotides at the site of gene-segment joining, as well as by somatic mutations that occur with very high frequency in the assembled V-region coding sequences after stimulation by antigen and helper T cells.

All B cells initially make IgM antibodies, and most then make IgD as well. Later many switch and make antibodies of other classes but with the same antigen-binding site as the original IgM and IgD antibodies. Such class switching depends on antigen stimulation and helper T cells, and it allows the same antigen-binding sites to be distributed among antibodies with varied biological properties.  [TOP](#)

Figure 24-38. The human heavy-chain gene-segment pool. There are 51 *V* segments, 27 *D* segments, 6 *J* segments, and an ordered cluster of *C*-region exons, each cluster encoding a different class of heavy chain. The *D* segment (and part of the *J* segment) encodes amino acids in the third hypervariable region, which is the most variable part of the *V* region. The figure is not drawn to scale: the total length of the heavy chain locus is over 2 megabases. Moreover, many details are omitted. For instance, each *C* region is encoded by multiple exons (see [Figure 24-33](#)); there are four clusters of C_{γ} region exons (C_{γ^1} , C_{γ^2} , C_{γ^3} , and C_{γ^4}), and the V_H gene segments are clustered on the

chromosome in groups of homologous families. The genetic mechanisms involved in producing a heavy chain are the same as those shown in [Figure 24-37](#) for light chains except that two DNA rearrangement steps are required instead of one. First a *D* segment joins to a *J* segment, and then a *V* segment joins to the rearranged *DJ* segment.

Figure 24-40. Antibody gene-pool selection in B cell development. To produce antibodies with only one type of antigen-binding site, a developing B cell must use only one L-chain gene-segment pool and one H-chain pool. Although the choice between maternal and paternal pools is thought to be random, the assembly of V-region coding sequences in a developing B cell proceeds in an orderly sequence, one segment at a time, usually beginning with the heavy-chain pool. In this pool, D segments first join to J_H segments on both parental chromosomes; then V_H to DJ_H joining occurs on one of these chromosomes (not shown). If this rearrangement produces a functional gene,

the resulting production of complete μ chains (always the first heavy chains made) leads to their expression on the cell surface in association with surrogate light chains. The cell now shuts down all further rearrangements of V_H -region-encoding gene segments and initiates V_L rearrangement. Although not shown, V_L rearrangement usually occurs first in a κ gene-segment pool, and only if that fails does it occur in the other κ pool or in the λ pools. If, at any point, "in-phase" V_L -to- J_L joining leads to the production of light chains, these combine with preexisting μ chains to form IgM antibody molecules, which insert into the plasma membrane. The IgM cell-surface receptors are thought to enable the newly formed B cell to receive extracellular signals that shut down all further $V(D)J$ joining, by turning off the expression of the *rag-1* and *rag-2* genes. If a developing B cell makes a receptor that recognizes a self-antigen, it is stimulated to re-express the *rag* genes and undergo another round of $V(D)J$ joining (called receptor editing), thereby changing the specificity of its receptor (not shown). If a cell fails to assemble both a functional V_H -region and a functional V_L -region coding sequence, it is unable to make antibody molecules and dies by apoptosis (not shown).

Figure 24-41. An example of the DNA rearrangement that occurs in class switch recombination. A B cell making an IgM antibody from an assembled VDJ DNA sequence is stimulated by antigen and the cytokines made by helper T cells to switch to making an IgA antibody. In the process, it deletes the DNA between the VDJ sequence and the C_α -coding sequence. Specific DNA sequences (*switch sequences*)

located upstream of each C_H -coding sequence recombine with each other to delete the intervening DNA. Class switch recombination is thought to be mediated by a *switch recombinase*, which is directed to the appropriate switch sequences when these become accessible under the influence of cytokines, as we discuss later.

Molecular Biology of the Cell ➔ V. Cells in Their Social Context ➔ 24. The Adaptive Immune System

T Cells and MHC Proteins

The diverse responses of T cells are collectively called *cell-mediated immune reactions*. This is to distinguish them from antibody responses, which, of course, also depend on cells (B cells). Like antibody responses, T cell responses are exquisitely antigen-specific, and they are at least as important as antibodies in defending vertebrates against infection. Indeed, most adaptive immune responses, including antibody responses, require helper T cells for their initiation. Most importantly, unlike B cells, T cells can help eliminate pathogens that reside inside host cells. Much of the rest of this chapter is concerned with how T cells accomplish this feat.

T cell responses differ from B cell responses in at least two crucial ways. First, T cells are activated by foreign antigen to proliferate and differentiate into effector cells only when the antigen is displayed on the surface of antigen-presenting cells in peripheral lymphoid organs. The T cells respond in this manner because the form of antigen they recognize is different from that recognized by B cells. Whereas B cells recognize intact antigen, T cells recognize fragments of protein antigens that have been partly degraded inside the antigen-presenting cell. The peptide fragments are then carried to the surface of the presenting cell on special molecules called *MHC proteins*, which present the fragments to T cells. The second difference is that, once activated, effector T cells act only at short range, either within a secondary lymphoid organ or after they have migrated into a site of infection. They interact directly with another cell in the body, which they either kill or signal in some way (we shall refer to such cells as *target cells*). Activated B cells, by contrast, secrete antibodies that can act far away.

There are two main classes of T cells—cytotoxic T cells and helper T cells. Effector *cytotoxic T cells* directly kill cells that are infected with a virus or some other intracellular pathogen. Effector *helper T cells*, by contrast, help stimulate the responses of other cells—mainly macrophages, B cells, and cytotoxic T cells.

In this section, we describe these two classes of T cells and their respective functions. We discuss how they recognize foreign antigens on the surface of antigen-presenting cells and target cells and consider the crucial part played by

MHC proteins in the recognition process. Finally, we describe how T cells are selected during their development in the thymus to ensure that only cells with potentially useful receptors survive and mature. We begin by considering the nature of the cell-surface receptors that T cells use to recognize antigen.

T Cell Receptors Are Antibodylike Heterodimers

Because T cell responses depend on direct contact with an antigen-presenting cell or a target cell, the antigen receptors made by T cells, unlike antibodies made by B cells, exist only in membrane-bound form and are not secreted. For this reason, T cell receptors were difficult to isolate, and it was not until the 1980s that they were first identified biochemically. On both cytotoxic and helper T cells, the receptors are similar to antibodies. They are composed of two disulfide-linked polypeptide chains (called α and β), each of which contains two Ig-like domains, one variable and one constant ([Figure 24-42A](#)). Moreover, the three-dimensional structure of the extracellular part of a T cell receptor has been determined by x-ray diffraction, and it looks very much like one arm of a Y-shaped antibody molecule ([Figure 24-42B](#)).

The pools of gene segments that encode the α and β chains are located on different chromosomes. Like antibody heavy-chain pools, the T cell receptor pools contain separate *V*, *D*, and *J* gene segments, which are brought together by site-specific recombination during T cell development in the thymus. With one exception, all the mechanisms used by B cells to generate antibody diversity are also used by T cells to generate T cell receptor diversity. Indeed, the same *V(D)J* recombinase is used, including the RAG proteins discussed earlier. The mechanism that does not operate in T cell receptor diversification is antigen-driven somatic hypermutation. Thus, the affinity of the receptors remains low ($K_a \sim 10^5$ - 10^7 liters/mole), even late in an immune response. We discuss later how various co-receptors and cell-cell adhesion mechanisms greatly strengthen the binding of a T cell to an antigen-presenting cell or a target cell, helping to compensate for the low affinity of the T cell receptors.

A small minority of T cells, instead of making α and β chains, make a different but related type of receptor heterodimer, composed of γ and δ chains. These cells arise early in development and are found mainly in epithelia (in the skin and gut, for example). Their functions are uncertain, and we shall not discuss them further.

As with antigen receptors on B cells, the T cell receptors are tightly associated in the plasma membrane with a number of invariant membrane-bound proteins that are involved in passing the signal from an antigen-activated receptor to the cell interior. We discuss these proteins in more detail later. First, however, we need to consider how cytotoxic and helper T cells function and the special ways in which they recognize foreign antigen. [↑ TOP](#)

Antigen-Presenting Cells Activate T Cells

Before cytotoxic or helper T cells can kill or help their target cells, respectively, they must be activated to proliferate and differentiate into effector cells. This activation occurs in peripheral lymphoid organs on the surface of antigen-presenting cells that display foreign antigen complexed with MHC proteins on their surface.

There are three main types of antigen-presenting cells in peripheral lymphoid organs that can activate T cells—dendritic cells, macrophages, and B cells. The most potent of these are dendritic cells (Figure 24-43), whose only known function is to present foreign antigens to T cells. Immature dendritic cells are located in tissues throughout the body, including the skin, gut, and respiratory tract. When they encounter invading microbes at these sites, they endocytose the pathogens or their products and carry them via the lymph to local lymph nodes or gut-associated lymphoid organs. The encounter with a pathogen induces the dendritic cell to mature from an antigen-capturing cell to an antigen-presenting cell that can activate T cells (see Figure 24-5).

Antigen-presenting cells display three types of protein molecules on their surface that have a role in activating a T cell to become an effector cell: (1) *MHC proteins*, which present foreign antigen to the T cell receptor, (2) *costimulatory proteins*, which bind to complementary receptors on the T cell surface, and (3) *cell-cell adhesion molecules*, which enable a T cell to bind to the antigen-presenting cell for long enough to become activated (Figure 24-44).

Before discussing the role of MHC proteins in presenting antigen to T cells, we consider the functions of the two major classes of T cells. [↑ TOP](#)

Effector Cytotoxic T Cells Induce Infected Target Cells to Kill Themselves

Cytotoxic T cells provide protection against intracellular pathogens such as viruses and some bacteria and parasites that multiply in the host-cell cytoplasm, where they are sheltered from attack by antibodies. They provide this protection by killing the infected cell before the microbes can proliferate and escape from the infected cell to infect neighboring cells.

Once a cytotoxic T cell has been activated by an infected antigen-presenting cell to become an effector cell, it can kill any target cell infected with the same pathogen. When the effector T cell recognizes a microbial antigen on the surface of an infected target cell, it focuses its secretory apparatus on the target. We can observe this behavior by studying effector T cells bound to their targets: when labeled with anti-tubulin antibodies, the T cell centrosome is seen to be oriented toward the point of contact with the target cell (Figure 24-45). Moreover, antibody labeling shows that talin and other proteins that help

link cell-surface receptors to cortical actin filaments are concentrated in the cortex of the T cell at the contact site. The aggregation of T cell receptors at the contact site apparently leads to a local alteration in the actin filaments in the cell cortex. A microtubule-dependent mechanism then moves the centrosome and its associated Golgi apparatus toward the contact site, focusing the killing machinery on the target cell. A similar cytoskeletal polarization is seen when an effector helper T cell interacts functionally with a target cell.

Once bound to its target cell, a cytotoxic T cell can employ at least two strategies to kill the target, both of which operate by inducing the target cell to kill itself by undergoing apoptosis (discussed in [Chapter 17](#)). In killing an infected target cell, the cytotoxic T cell usually releases a pore-forming protein called **perforin**, which is homologous to the complement component C9 (see [Figure 25-42](#)) and polymerizes in the target cell plasma membrane to form transmembrane channels. Perforin is stored in secretory vesicles of the cytotoxic T cell and is released by local exocytosis at the point of contact with the target cell. The secretory vesicles also contain serine proteases, which are thought to enter the target cell cytosol through the perforin channels. One of the proteases, called *granzyme B*, cleaves, and thereby activates, one or more members of the *caspase family* of proteases that mediate apoptosis. These caspases then activate other caspases, producing a proteolytic cascade that helps kill the cell (discussed in [Chapter 17](#)) ([Figure 24-46A](#)). Mice in which the perforin gene is inactivated cannot generate microbe-specific cytotoxic T cells and show increased susceptibility to certain viral and intracellular bacterial infections.

In the second killing strategy, the cytotoxic T cell also activates a death-inducing caspase cascade in the target cell but does it less directly. A homotrimeric protein on the cytotoxic T cell surface called **Fas ligand** binds to transmembrane receptor proteins on the target cell called **Fas**. The binding alters the Fas proteins so that their clustered cytosolic tails recruit procaspase-8 into the complex via an adaptor protein. The recruited procaspase-8 molecules cross-cleave and activate each other to begin the caspase cascade that leads to apoptosis ([Figure 24-46B](#)). Cytotoxic T cells apparently use this killing strategy to help contain an immune response once it is well underway, by killing excessive effector lymphocytes, especially effector T cells: if the gene encoding either Fas or Fas ligand is inactivated by mutation, effector lymphocytes accumulate in vast numbers in the spleen and lymph nodes, which become enormously enlarged. [↑ TOP](#)

Effector Helper T Cells Help Activate Macrophages, B Cells, and Cytotoxic T Cells

In contrast to cytotoxic T cells, [helper T cells](#) are crucial for defense against both extracellular and intracellular pathogens. They help stimulate B cells to make antibodies that help inactivate or eliminate extracellular pathogens and their toxic products. They activate macrophages to destroy any intracellular

pathogen multiplying within the macrophage's phagosomes, and they help activate cytotoxic T cells to kill infected target cells.

Once a helper T cell has been activated by an antigen-presenting cell to become an effector cell, it can then help activate other cells. It does this both by secreting a variety of cytokines and by displaying costimulatory proteins on its surface. When activated by an antigen-presenting cell, a naïve helper T cell can differentiate into either of two distinct types of effector helper cell, called T_H1 and T_H2 . T_H1 cells mainly help activate macrophages and cytotoxic T cells, whereas T_H2 cells mainly help activate B cells ([Figure 24-47](#)). As we

discuss later, the nature of the invading pathogen and the types of innate immune responses it elicits largely determine which type of helper T cell develops. This, in turn, determines the nature of the adaptive immune responses mobilized to fight the invaders.

Before discussing how helper T cells function to activate macrophages, cytotoxic T cells, or B cells, we need to consider the crucial role of MHC proteins in T cell responses. [↑ TOP](#)

T Cells Recognize Foreign Peptides Bound to MHC Proteins

As discussed earlier, both cytotoxic T cells and helper T cells are initially activated in peripheral lymphoid organs by recognizing foreign antigen on the surface of an antigen-presenting cell, usually a dendritic cell. The antigen is in the form of peptide fragments that are generated by the degradation of foreign protein antigens inside the antigen-presenting cell. The recognition process depends on the presence in the antigen-presenting cell of **MHC proteins**, which bind these fragments, carry them to the cell surface, and present them there, along with a co-stimulatory signal, to the T cells. Once activated, effector T cells then recognize the same peptide-MHC complex on the surface of the target cell they influence, which may be a B cell, a cytotoxic T cell, or an infected macrophage in the case of a helper T cell, or a virus-infected cell in the case of a cytotoxic T cell.

MHC proteins are encoded by a large complex of genes called the **major histocompatibility complex (MHC)**. There are two main structurally and functionally distinct classes of MHC proteins: *class I MHC proteins*, which present foreign peptides to cytotoxic T cells, and *class II MHC proteins*, which present foreign peptides to helper cells ([Figure 24-48](#)).

Before examining the different mechanisms by which protein antigens are processed for display to the two main classes of T cells, we must look more closely at the MHC proteins themselves, which have such an important role in T cell function. [↑ TOP](#)

MHC Proteins Were Identified in Transplantation Reactions Before Their Functions Were Known

MHC proteins were initially identified as the main antigens recognized in **transplantation reactions**. When organ grafts are exchanged between adult individuals, either of the same species (*allografts*) or of different species (*xenografts*), they are usually rejected. In the 1950s, skin grafting experiments between different strains of mice demonstrated that *graft rejection* is an adaptive immune response to the foreign antigens on the surface of the grafted cells. Rejection is mediated mainly by T cells, which react against genetically "foreign" versions of cell-surface proteins called *histocompatibility molecules* (from the Greek word *histos*, meaning "tissue"). The MHC proteins encoded by the clustered genes of the major histocompatibility complex (MHC) are by far the most important of these. MHC proteins are expressed on the cells of all higher vertebrates. They were first demonstrated in mice, where they are called *H-2 antigens* (histocompatibility-2 antigens). In humans they are called *HLA antigens* (human-leucocyte-associated antigens) because they were first demonstrated on leucocytes (white blood cells).

Three remarkable properties of MHC proteins baffled immunologists for a long time. First, MHC proteins are overwhelmingly the preferred antigens recognized in T-cell-mediated transplantation reactions. Second, an unusually large fraction of T cells are able to recognize foreign MHC proteins: whereas fewer than 0.001% of an individual's T cells respond to a typical viral antigen, more than 0.1% of them respond to a single foreign MHC antigen. Third, some of the genes that code for MHC proteins are the most *polymorphic* known in higher vertebrates. That is, within a species, there is an extraordinarily large number of *alleles* (alternative forms of the same gene) present (in some cases more than 200), without any one allele predominating. As each individual has at least 12 genes encoding MHC proteins (see later), it is very rare for two unrelated individuals to have an identical set of MHC proteins. This makes it very difficult to match donor and recipient for organ transplantation unless they are closely related.

Of course, a vertebrate does not need to protect itself against invasion by foreign vertebrate cells. So the apparent obsession of its T cells with foreign MHC proteins and the extreme polymorphism of these molecules were a great puzzle. The puzzle was solved only after it was discovered that (1) MHC proteins bind fragments of foreign proteins and display them on the surface of host cells for T cells to recognize, and (2) T cells respond to foreign MHC proteins in the same way they respond to self MHC proteins that have foreign antigen bound to them.  [TOP](#)

Class I and Class II MHC Proteins Are Structurally Similar Heterodimers

Class I and class II MHC proteins have very similar overall structures. They

are both transmembrane heterodimers with extracellular N-terminal domains that bind antigen for presentation to T cells.

Class I MHC proteins consist of a transmembrane α chain, which is encoded by a class I MHC gene, and a small extracellular protein called β_2 -

microglobulin (Figure 24-49A). The β_2 -microglobulin does not span the membrane and is encoded by a gene that does not lie in the MHC gene cluster. The α chain is folded into three extracellular globular domains (α_1 , α_2 , α_3), and the α_3 domain and the β_2 -microglobulin, which are closest to the membrane, are both similar to an Ig domain. The two N-terminal domains of the α chain, which are farthest from the membrane, contain the polymorphic (variable) amino acids that are recognized by T cells in transplantation reactions. These domains bind a peptide and present it to cytotoxic T cells.

Like class I MHC proteins, **class II MHC proteins** are heterodimers with two conserved Ig-like domains close to the membrane and two polymorphic (variable) N-terminal domains farthest from the membrane. In these proteins, however, both chains (α and β) are encoded by genes within the MHC, and both span the membrane (Figure 24-49B). The two polymorphic domains bind a peptide and present it to helper T cells.

The presence of Ig-like domains in class I and class II proteins suggests that MHC proteins and antibodies have a common evolutionary history. The locations of the genes that encode class I and class II MHC proteins in humans are shown in Figure 24-50, where we illustrate how an individual can make six types of class I MHC proteins and more than six types of class II proteins.

In addition to the classic class I MHC proteins, there are many *nonclassical class I MHC proteins*, which form dimers with β_2 -microglobulin. These proteins are not polymorphic, but some of them present specific microbial antigens, including some lipids and glycolipids, to T cells. The functions of most of them, however, are unknown. [↑ TOP](#)

An MHC Protein Binds a Peptide and Interacts with a T Cell Receptor

Any individual can make only a small number of different MHC proteins, which together must be able to present peptide fragments from almost any foreign protein to T cells. Thus, unlike an antibody molecule, each MHC protein has to be able to bind a very large number of different peptides. The structural basis for this versatility has emerged from x-ray crystallographic analyses of MHC proteins.

As shown in Figure 24-51A, a class I MHC protein has a single peptide-

binding site located at one end of the molecule, facing away from the plasma membrane. This site consists of a deep groove between two long α helices; the groove narrows at both ends so that it is only large enough to accommodate an extended peptide about 8–10 amino acids long. In fact, when a class I MHC protein was first analyzed by x-ray crystallography in 1987, this groove contained bound peptides that had co-crystallized with the MHC protein ([Figure 24-51B](#)), suggesting that once a peptide binds to this site it does not normally dissociate.

A typical peptide binds in the groove of a class I MHC protein in an extended conformation, with its terminal amino group bound to an invariant pocket at one end of the groove and its terminal carboxyl group bound to an invariant pocket at the other end of the groove. Other amino acids (called "anchor amino acids") in the peptide bind to "specificity pockets" in the groove formed by polymorphic portions of the MHC protein ([Figure 24-52](#)). The side chains of other amino acids of the peptide point outward, in a position to be recognized by receptors on cytotoxic T cells. Because the conserved pockets at the ends of the binding groove recognize features of the peptide backbone that are common to all peptides, each allelic form of a class I MHC protein can bind a large variety of peptides of diverse sequence. At the same time, the differing specificity pockets along the groove, which bind particular amino acid side chains of the peptide, ensure that each allelic form binds and presents a distinct characteristic set of peptides. Thus, the six types of class I MHC proteins in an individual can present a broad range of foreign peptides to the cytotoxic T cells, but in each individual they do so in slightly different ways.

Class II MHC proteins have a three-dimensional structure that is very similar to that of class I proteins, but their antigen-binding groove does not narrow at the ends, so it can accommodate longer peptides, which are usually 13–17 amino acids long. Moreover, the peptide is not bound at its ends. It is held in the groove by parts of its peptide backbone that bind to invariant pockets formed by conserved amino acids that line all class II MHC peptide-binding grooves, as well as by the side chains of anchor amino acids that bind to variable specificity pockets in the groove ([Figure 24-53](#)). A class II MHC binding groove can accommodate a more heterogeneous set of peptides than can a class I MHC groove. Thus, although an individual makes only a small number of types of class II proteins, each with its own unique peptide-binding groove, together these proteins can bind and present an enormous variety of foreign peptides to helper T cells, which have a crucial role in almost all adaptive immune responses.

The way in which the T cell receptor recognizes a peptide fragment bound to an MHC protein is revealed by x-ray crystallographic analyses of complexes formed between a soluble receptor and a soluble MHC protein with peptide in its binding groove. (The soluble proteins for these experiments are produced by recombinant DNA technology.) In each case studied, the T cell receptor fits diagonally across the peptide-binding groove and binds through its V_{α} and V_{β}

hypervariable loops to both the walls of the groove and the peptide ([Figure 24-54](#)). Soluble MHC-peptide complexes are now widely used to detect T cells with a particular specificity; they are usually cross-linked into tetramers to increase their avidity for T cell receptors. [↑ TOP](#)

MHC Proteins Help Direct T Cells to Their Appropriate Targets

Class I MHC proteins are expressed on virtually all nucleated cells. This is presumably because effector cytotoxic T cells must be able to focus on and kill any cell in the body that happens to become infected with an intracellular microbe such as a virus. Class II proteins, by contrast, are normally confined largely to cells that take up foreign antigens from the extracellular fluid and interact with helper T cells. These include dendritic cells, which initially activate helper T cells, as well as the targets of effector helper T cells, such as macrophages and B cells. Because dendritic cells express both class I and class II MHC proteins, they can activate both cytotoxic and helper T cells.

It is important that effector cytotoxic T cells focus their attack on cells that *make* the foreign antigens (such as viral proteins), while helper T cells focus their help mainly on cells that have taken up foreign antigens from the extracellular fluid. Since the former type of target cell is always a menace, while the latter type is essential for the body's immune defenses, it is vitally important that T cells never confuse the two target cells and misdirect their cytotoxic and helper functions. Therefore, in addition to the antigen receptor that recognizes a peptide-MHC complex, each of the two major classes of T cells also expresses a *co-receptor* that recognizes a separate, invariant part of the appropriate class of MHC protein. These two co-receptors, called CD4 and CD8, help direct helper T cells and cytotoxic T cells, respectively, to their appropriate targets, as we now discuss. The properties of class I and class II MHC proteins are compared in [Table 24-2](#).

CD4 and CD8 Co-receptors Bind to Nonvariable Parts of MHC Proteins

The affinity of T cell receptors for peptide-MHC complexes on an antigen-presenting cell or target cell is usually too low to mediate a functional interaction between the two cells by itself. T cells normally require *accessory receptors* to help stabilize the interaction by increasing the overall strength of the cell-cell adhesion. Unlike T cell receptors or MHC proteins, the accessory receptors do not bind foreign antigens and are invariant.

When accessory receptors also have a direct role in activating the T cell by generating their own intracellular signals, they are called **co-receptors**. The most important and best understood of the co-receptors on T cells are the CD4 and CD8 proteins, both of which are single-pass transmembrane proteins with

extracellular Ig-like domains. Like T cell receptors, they recognize MHC proteins, but, unlike T cell receptors, they bind to nonvariable parts of the protein, far away from the peptide-binding groove. CD4 is expressed on helper T cells and binds to class II MHC proteins, whereas CD8 is expressed on cytotoxic T cells and binds to class I MHC proteins (Figure 24-55). Thus, CD4 and CD8 contribute to T cell recognition by helping to focus the cell on particular MHC proteins, and thus on particular types of cells—helper T cells on dendritic cells, macrophages, and B cells, and cytotoxic cells on any nucleated host cell displaying a foreign peptide on a class I MHC protein. The cytoplasmic tail of these transmembrane proteins is associated with a member of the Src family of cytoplasmic tyrosine protein kinases called *Lck*, which phosphorylates various intracellular proteins on tyrosines and thereby participates in the activation of the T cell. Antibodies to CD4 and CD8 are widely used as tools to distinguish between the two main classes of T cells, in both humans and experimental animals.

Ironically, the AIDS virus (HIV) makes use of CD4 molecules (as well as chemokine receptors) to enter helper T cells. It is the eventual depletion of helper T cells that renders AIDS patients susceptible to infection by microbes that are not normally dangerous. As a result, most AIDS patients die of infection within several years of the onset of symptoms, unless they are treated with a combination of powerful anti-HIV drugs. HIV also uses CD4 and chemokine receptors to enter macrophages, which also have both of these receptors on their surface.

Before a cytotoxic or helper T cell can recognize a foreign protein, the protein has to be processed inside an antigen-presenting cell or target cell so that it can be displayed as peptide-MHC complexes on the cell surface. We first consider how a virus-infected antigen-presenting cell or target cell processes viral proteins for presentation to a cytotoxic T cell. We then discuss how ingested foreign proteins are processed for presentation to a helper T cell. [↑ TOP](#)

Cytotoxic T Cells Recognize Fragments of Foreign Cytosolic Proteins in Association with Class I MHC Proteins

One of the first, and most dramatic, demonstrations that MHC proteins present foreign antigens to T cells came from an experiment performed in the 1970s. It was found that effector cytotoxic T cells from a virus-infected mouse could kill cultured cells infected with the same virus only if these target cells expressed some of the same class I MHC proteins as the infected mouse (Figure 24-56). This experiment demonstrated that the T cells of any individual that recognize a specific antigen do so only when that antigen is associated with the allelic forms of MHC proteins expressed by that individual, a phenomenon known as *MHC restriction*.

The chemical nature of the viral antigens recognized by cytotoxic T cells was not discovered for another 10 years. In experiments on cells infected with

influenza virus, it was unexpectedly found that some of the effector cytotoxic T cells activated by the virus specifically recognize internal proteins of the virus that would not be accessible in the intact virus particle. Subsequent evidence indicated that the T cells were recognizing degraded fragments of the internal viral proteins that were bound to class I MHC proteins on the infected cell surface. Because a T cell can recognize tiny amounts of antigen (as few as one hundred peptide-MHC complexes), only a small fraction of the fragments generated from viral proteins have to bind to class I MHC proteins and get to the cell surface to attract an attack by an effector cytotoxic T cell.

The viral proteins are synthesized in the cytosol of the infected cell. As discussed in [Chapter 3](#), proteolytic degradation in the cytosol is mainly mediated by an ATP- and ubiquitin-dependent mechanism that operates in *proteasomes*—large proteolytic enzyme complexes constructed from many different protein subunits. Although all proteasomes are probably able to generate peptide fragments that can bind to class I MHC proteins, some proteasomes are thought to be specialized for this purpose, as they contain two subunits that are encoded by genes located within the MHC chromosomal region. Even bacterial proteasomes cut proteins into peptides of about the length that fits into the groove of a class I MHC protein, suggesting that the MHC groove evolved to fit this length of peptide.

How do peptides generated in the cytosol make contact with the peptide-binding groove of class I MHC proteins in the lumen of the endoplasmic reticulum ([Figure 24-57](#))? The answer was discovered through observations on mutant cells in which class I MHC proteins are not expressed at the cell surface but are instead degraded within the cell. The mutant genes in these cells proved to encode subunits of a protein belonging to the family of *ABC transporters*, which we discuss in [Chapter 11](#). This transporter protein is located in the ER membrane and uses the energy of ATP hydrolysis to pump peptides from the cytosol into the ER lumen. The genes encoding its two subunits are in the MHC chromosomal region, and, if either gene is inactivated by mutation, cells are unable to supply peptides to class I MHC proteins. The class I MHC proteins in such mutant cells are degraded in the cell because peptide binding is normally required for the proper folding of these proteins. Until it binds a peptide, a class I MHC protein remains in the ER, tethered to an ABC transporter by a chaperone protein ([Figure 24-58](#)).

In cells that are not infected, peptide fragments come from the cells' own cytosolic and nuclear proteins that are degraded in the processes of normal protein turnover and quality control mechanisms. (Surprisingly, more than 30% of the proteins made by mammalian cells are apparently faulty and are degraded in proteasomes soon after they are synthesized.) These peptides are pumped into the ER and are carried to the cell surface by class I MHC proteins. They are not antigenic because the cytotoxic T cells that could recognize them have been eliminated or inactivated during T cell development, as we discuss later.

When cytotoxic T cells and some helper T cells are activated by antigen to become effector cells, they secrete the cytokine **interferon- γ (IFN- γ)**, which greatly enhances anti-viral responses. The IFN- γ acts on infected cells in two ways. It blocks viral replication, and it increases the expression of many genes within the MHC chromosomal region. These genes include those that encode class I (and class II) MHC proteins, the two specialized proteasome subunits, and the two subunits of the peptide transporter located in the ER ([Figure 24-59](#)). Thus, all of the machinery required for presenting viral antigens to cytotoxic T cells is coordinately called into action by IFN- γ , creating a positive feedback that amplifies the immune response and culminates in the death of the infected cells.  [TOP](#)

Helper T Cells Recognize Fragments of Endocytosed Foreign Protein Associated with Class II MHC Proteins

Unlike cytotoxic T cells, helper T cells do not act directly to kill infected cells so as to eliminate microbes. Instead, they stimulate macrophages to be more effective in destroying intracellular microorganisms, and they help B cells and cytotoxic T cells to respond to microbial antigens.

Like the viral proteins presented to cytotoxic T cells, the proteins presented to helper T cells on antigen-presenting cells or target cells are degraded fragments of foreign proteins. The fragments are bound to class II MHC proteins in much the same way that virus-derived peptides are bound to class I MHC proteins. But both the source of the peptide fragments presented and the route they take to find the MHC proteins are different from those of peptide fragments presented by class I MHC proteins to cytotoxic T cells.

Rather than being derived from foreign protein synthesized in the cytosol of a cell, the foreign peptides presented to helper T cells are derived from endosomes. Some come from extracellular microbes or their products that the antigen-presenting cell has endocytosed and degraded in the acidic environment of its endosomes. Others come from microbes growing within the endocytic compartment of the antigen-presenting cell. These peptides do not have to be pumped across a membrane because they do not originate in the cytosol; they are generated in a compartment that is topologically equivalent to the extracellular space. They never enter the lumen of the ER, where the class II MHC proteins are synthesized and assembled, but instead bind to preassembled class II heterodimers in a special endosomal compartment. Once the peptide has bound, the class II MHC protein alters its conformation, trapping the peptide in the binding groove for presentation at the cell surface to helper T cells.

A newly synthesized class II MHC protein must avoid clogging its binding groove prematurely in the ER lumen with peptides derived from endogenously synthesized proteins. A special polypeptide, called the **invariant chain**, ensures this by associating with newly synthesized class II MHC heterodimers

in the ER. Part of its polypeptide chain lies within the peptide-binding groove of the MHC protein, thereby blocking the groove from binding other peptides in the lumen of the ER. The invariant chain also directs class II MHC proteins from the *trans* Golgi network to a late endosomal compartment. Here, the invariant chain is cleaved by proteases, leaving only a short fragment bound in the peptide-binding groove of the MHC protein. This fragment is then released (catalyzed by a class II-MHC-like protein called HLA-DM), freeing the MHC protein to bind peptides derived from endocytosed proteins (Figure 24-60). In this way, the functional differences between class I and class II MHC proteins are ensured—the former presenting molecules that come from the cytosol, the latter presenting molecules that come from the endocytic compartment.

Most of the class I and class II MHC proteins on the surface of a target cell have peptides derived from self proteins in their binding groove. For class I proteins, the fragments derive from degraded cytosolic and nuclear proteins. For class II proteins, they mainly derive from degraded proteins that originate in the plasma membrane or extracellular fluid and are endocytosed. Only a small fraction of the 10^5 or so class II MHC proteins on the surface of an antigen-presenting cell have foreign peptides bound to them. This is sufficient, however, because only a hundred or so of such molecules are required to stimulate a helper T cell, just as in the case of peptide-class-I-MHC complexes stimulating a cytotoxic T cell. [↑ TOP](#)

Potentially Useful T Cells Are Positively Selected in the Thymus

We have seen that T cells recognize antigen in association with self MHC proteins but not in association with foreign MHC proteins (see Figure 24-56): that is, T cells show *MHC restriction*. This restriction results from a process of **positive selection** during T cell development in the thymus. In this process, those immature T cells that will be capable of recognizing foreign peptides presented by self MHC proteins are selected to survive, while the remainder, which would be of no use to the animal, undergo apoptosis. Thus, MHC restriction is an acquired property of the immune system that emerges as T cells develop in the thymus.

The most direct way to study the selection process is to follow the fate of a set of developing T cells of known specificity. This can be done by using transgenic mice that express a specific pair of rearranged α and β T cell receptor genes derived from a T cell clone of known antigen and MHC specificity. Such experiments show that the transgenic T cells mature in the thymus and populate the peripheral lymphoid organs only if the transgenic mouse also expresses the same allelic form of MHC protein as is recognized by the transgenic T cell receptor. If the mouse does not express the appropriate MHC protein, the transgenic T cells die in the thymus. Thus, the survival and maturation of a T cell depend on a match between its receptor and the MHC proteins expressed in the thymus. Similar experiments using transgenic mice in

which MHC expression is confined to specific cell types in the thymus indicate that it is MHC proteins on epithelial cells in the cortex of the thymus that are responsible for this positive selection process. After positively selected T cells leave the thymus, their continued survival depends on their continual stimulation by self-peptide-MHC complexes; this stimulation is enough to promote cell survival but not enough to activate the T cells to become effector cells.

As part of the positive selection process in the thymus, developing T cells that express receptors recognizing class I MHC proteins are selected to become cytotoxic cells, while T cells that express receptors recognizing class II MHC proteins are selected to become helper cells. Thus, genetically engineered mice that lack cell-surface class I MHC proteins specifically lack cytotoxic T cells, whereas mice that lack class II MHC proteins specifically lack helper T cells. The cells that are undergoing positive selection initially express both CD4 and CD8 co-receptors, and these are required for the selection process: without CD4, helper T cells fail to develop, and without CD8, cytotoxic T cells fail to develop.

Positive selection still leaves a large problem to be solved. If developing T cells with receptors that recognize self peptides associated with self MHC proteins were to mature in the thymus and migrate to peripheral lymphoid tissues, they might wreak havoc. A second, *negative selection* process in the thymus is required to help avoid this potential disaster. [↑ TOP](#)

Many Developing T Cells That Could Be Activated by Self Peptides Are Eliminated in the Thymus

As discussed previously, a fundamental feature of the adaptive immune system is that it can distinguish self from nonself and normally does not react against self molecules. An important mechanism in achieving this state of *immunological self tolerance* is the deletion in the thymus of developing self-reactive T cells—that is, T cells whose receptors bind strongly enough to the complex of a self peptide and a self MHC protein to become activated. Because, as we discuss later, most B cells require helper T cells to respond to antigen, the elimination of self-reactive helper T cells also helps ensure that self-reactive B cells that escape B cell tolerance induction are harmless.

It is not enough, therefore, for the thymus to select *for* T cells that recognize self MHC proteins; it must also select *against* T cells that could be activated by self MHC proteins complexed with self peptides. In other words, it must pick out for survival just those T cells that will be capable of responding to self MHC proteins complexed with foreign peptides, even though these peptides are not present in the developing thymus. It is thought that these T cells bind weakly in the thymus to self MHC proteins that are carrying self peptides mismatched to the T cell receptors. Thus, the required goal can be achieved by (1) ensuring the death of T cells that bind *strongly* to the self-peptide-MHC

complexes in the thymus while (2) promoting the survival of those that bind weakly and (3) permitting the death of those that do not bind at all. Process 2 is the positive selection we have just discussed. Process 1 is called **negative selection**. In both death processes, the cells that die undergo apoptosis ([Figure 24-61](#)).

The most convincing evidence for negative selection derives once again from experiments with transgenic mice. After the introduction of T cell receptor transgenes encoding a receptor that recognizes a male-specific peptide antigen, for example, large numbers of mature T cells expressing the transgenic receptor are found in the thymus and peripheral lymphoid organs of female mice. Very few, however, are found in male mice, where the cells die in the thymus before they have a chance to mature. Like positive selection, negative selection requires the interaction of a T cell receptor and a CD4 or CD8 co-receptor with an appropriate MHC protein. Unlike positive selection, however, which occurs mainly on the surface of thymus epithelial cells, negative selection occurs on the surface of thymus dendritic cells and macrophages, which, as we have seen, function as antigen-presenting cells in peripheral lymphoid organs.

The deletion of self-reactive T cells in the thymus cannot eliminate all potentially self-reactive T cells, as some self molecules are not present in the thymus. Thus, some potentially self-reactive T cells are deleted or functionally inactivated after they leave the thymus, presumably because they recognize self peptides bound to MHC proteins on the surface of dendritic cells that have not been activated by microbes and therefore do not provide a costimulatory signal. As we discuss later, antigen recognition without costimulatory signals can delete or inactivate a T or B cell.

Some potentially self-reactive T cells, however, are not deleted or inactivated. Instead, special *regulatory* (or *suppressor*) *T cells* are thought to keep them from responding to their self antigens by secreting inhibitory cytokines such as TGF- β (discussed in [Chapter 15](#)). These self-reactive T cells may sometimes escape from this suppression and cause autoimmune diseases. [↑ TOP](#)

The Function of MHC Proteins Explains Their Polymorphism

The role of MHC proteins in binding foreign peptides and presenting them to T cells provides an explanation for the extensive polymorphism of these proteins. In the evolutionary war between pathogenic microbes and the adaptive immune system, microbes tend to change their antigens to avoid associating with MHC proteins. When a microbe succeeds, it is able to sweep through a population as an epidemic. In such circumstances, the few individuals that produce a new MHC protein that can associate with an antigen of the altered microbe have a large selective advantage. In addition, individuals with two different alleles at any given MHC locus (heterozygotes) have a better chance

of resisting infection than those with identical alleles at the locus, as they have a greater capacity to present peptides from a wide range of microbes and parasites. Thus, selection will tend to promote and maintain a large diversity of MHC proteins in the population. Strong support for this hypothesis, that infectious diseases have provided the driving force for MHC polymorphism, has come from studies in West Africa. Here, it is found that individuals with a specific MHC allele have a reduced susceptibility to a severe form of malaria. Although the allele is rare elsewhere, it is found in 25% of the West African population where this form of malaria is common.

If greater MHC diversity means greater resistance to infection, why do we each have so few MHC genes encoding these molecules? Why have we not evolved strategies for increasing the diversity of MHC proteins—by alternative RNA splicing, for example, or by the genetic recombination mechanisms used to diversify antibodies and T cell receptors? Presumably, the limits exist because each time a new MHC protein is added to the repertoire, the T cells that recognize self peptides in association with the new MHC protein must be eliminated to maintain self tolerance. The elimination of these T cells would counteract the advantage of adding the new MHC protein. Thus, the number of MHC proteins we express may represent a balance between the advantages of presenting a wide diversity of foreign peptides to T cells against the disadvantages of severely restricting the T cell repertoire during negative selection in the thymus. This explanation is supported by computer modeling studies.  [TOP](#)

Summary

There are two main functionally distinct classes of T cells: cytotoxic T cells kill infected cells directly by inducing them to undergo apoptosis, while helper T cells help activate B cells to make antibody responses and macrophages to destroy microorganisms that either invaded the macrophage or were ingested by it. Helper T cells also help activate cytotoxic T cells. Both classes of T cells express cell-surface, antibodylike receptors, which are encoded by genes that are assembled from multiple gene segments during T cell development in the thymus. These receptors recognize fragments of foreign proteins that are displayed on the surface of host cells in association with MHC proteins. Both cytotoxic and helper T cells are activated in peripheral lymphoid organs by antigen-presenting cells, which express peptide-MHC complexes, costimulatory proteins, and various cell-cell adhesion molecules on their cell surface.

Class I and class II MHC proteins have crucial roles in presenting foreign protein antigens to cytotoxic and helper T cells, respectively. Whereas class I proteins are expressed on almost all vertebrate cells, class II proteins are normally restricted to those cell types that interact with helper T cells, such as dendritic cells, macrophages, and B lymphocytes. Both classes of MHC proteins have a single peptide-binding groove, which binds small peptide fragments derived from proteins. Each MHC protein can bind a large and

characteristic set of peptides, which are produced intracellularly by protein degradation: class I MHC proteins generally bind fragments produced in the cytosol, while class II MHC proteins bind fragments produced in the endocytic compartment. After they have formed inside the target cell, the peptide-MHC complexes are transported to the cell surface. Complexes that contain a peptide derived from a foreign protein are recognized by T cell receptors, which interact with both the peptide and the walls of the peptide-binding groove. T cells also express CD4 or CD8 co-receptors, which recognize nonpolymorphic regions of MHC proteins on the target cell: helper cells express CD4, which recognizes class II MHC proteins, while cytotoxic T cells express CD8, which recognizes class I MHC proteins.

The T cell receptor repertoire is shaped mainly by a combination of positive and negative selection processes that operate during T cell development in the thymus. These processes help to ensure that only T cells with potentially useful receptors survive and mature, while the others die by apoptosis. T cells that will be able to respond to foreign peptides complexed with self MHC proteins are positively selected, while many T cells that could react strongly with self peptides complexed with self MHC proteins are eliminated. T cells with receptors that could react strongly with self antigens not present in the thymus are eliminated, functionally inactivated, or actively kept suppressed after they leave the thymus. Figure 24-42. A T cell receptor heterodimer. (A) Schematic drawing showing that the receptor is composed of an α and a β polypeptide chain. Each chain is about 280 amino acids long and has a large extracellular part that is folded into two Ig-like domains—one variable (V) and one constant (C). The antigen-binding site is formed by a V_α and a V_β domain (shaded in blue). Unlike antibodies, which

have two binding sites for antigen, T cell receptors have only one. The $\alpha\beta$ heterodimer is noncovalently associated with a large set of invariant membrane-bound proteins (not shown), which help activate the T cell when the T cell receptors bind to antigen. A typical T cell has about 30,000 such receptor complexes on its surface. (B) The three-dimensional structure of the extracellular part of a T cell receptor. The antigen-binding site is formed by the hypervariable loops of both the V_α and V_β domains (red), and it is similar in its overall

dimensions and geometry to the antigen-binding site of an antibody molecule. (B, based on K.C. Garcia et al., *Science* 274:209–219, 1996.)

Figure 24-46. Two strategies by which effector cytotoxic T cells kill their target cells. (A) The cytotoxic T cell (T_C) releases perforin and proteolytic enzymes onto the surface of an infected target cell by localized exocytosis. The high concentration of Ca^{2+} in the extracellular fluid causes the perforin to assemble into transmembrane channels, which are thought to allow the proteolytic enzymes to enter the target cell cytosol. One of the enzymes, granzyme B, cleaves and activates specific procaspases, thereby triggering the proteolytic caspase cascade leading to apoptosis. (B) The homotrimeric Fas ligand on the cytotoxic T cell surface binds to and activates Fas receptor protein on the surface of a target cell. The cytosolic tail of Fas contains a *death domain*, which, when activated, binds to an adaptor protein, which in turn recruits a specific procaspase (procaspase-8). Clustered procaspase-8 molecules then cleave one another to produce active caspase-8 molecules that initiate the proteolytic caspase cascade leading to apoptosis.

Figure 24-49. Class I and class II MHC proteins. (A) The α chain of the class I molecule has three extracellular domains, α_1 , α_2 and α_3 , encoded by separate exons. It is noncovalently associated with a smaller polypeptide chain, β_2 -microglobulin, which is not encoded within the MHC. The α_3 domain and β_2 -microglobulin are Ig-like. While β_2 -microglobulin is invariant, the α chain is extremely polymorphic, mainly in the α_1 and α_2 domains. (B) In class II MHC proteins, both chains are polymorphic, mainly in the α_1 and β_1 domains; the α_2 and β_2 domains are Ig-like. Thus, there are striking similarities between class I and class II MHC proteins. In both, the two outermost domains (shaded in blue) interact to form a groove that binds peptide fragments of foreign proteins and presents them to T cells

Figure 24-50. Human MHC genes. This simplified schematic drawing shows the location of the genes that encode the transmembrane subunits of class I (*light green*) and class II (*dark green*) MHC proteins. The genes shown encode three types of class I proteins (HLA-A, HLA-B, and HLA-C) and three types of class II MHC proteins (HLA-DP, HLA-DQ, and HLA-DR). An individual can therefore make six types of class I MHC proteins (three encoded by maternal genes and three by paternal genes) and more than six types of class II MHC proteins. The number of class II MHC proteins that can be made is increased because there are two DR β genes and because maternally encoded and paternally encoded polypeptide chains can sometimes pair.

Figure 24-56. The classic experiment showing that an effector cytotoxic T cell recognizes some aspect of the surface of the host target cell in addition to a viral antigen. Mice of strain X are infected with virus A. Seven days later, the spleens of these mice contain effector cytotoxic T cells able to kill virus-infected, strain-X fibroblasts in cell culture. As expected, they kill only fibroblasts infected with virus A and not those infected with virus B. Thus, the cytotoxic T cells are virus-specific. The same T cells, however, are also unable to kill fibroblasts from strain-Y mice infected with the same virus A, indicating that the cytotoxic T cells recognize a genetic difference between the two kinds of fibroblasts and not just the virus. Pinning down the difference required the use of special strains of mice (known as *congenic strains*) that either were genetically identical except for the alleles at their class I MHC loci or were genetically different except for these alleles. In this way, it was found that the killing of infected target cells required that they express at least one of the same class I MHC alleles as expressed by the original infected mouse. This suggested that class I MHC proteins are necessary to present cell-surface-bound viral antigens to effector cytotoxic T cells.

Figure 24-58. The processing of a viral protein for presentation to cytotoxic T cells. An effector cytotoxic T cell kills a virus-infected cell when it recognizes fragments of viral protein bound to class I MHC proteins on the surface of the infected cell. Not all viruses enter the cell in the way that this enveloped RNA virus does, but fragments of internal viral proteins always follow the pathway shown. Some of the viral proteins synthesized in the cytosol are degraded, and this is a sufficient amount to attract an attack by a cytotoxic T cell. The folding and assembly of a class I MHC protein is aided by several chaperone proteins in the ER lumen, only one of which is shown. The chaperones bind to the class I MHC α chain and act sequentially. The last one binds the MHC protein to the ABC transporter, as shown.

simplified view of how peptide-class-II-MHC complexes are formed in endosomes and delivered to the cell surface. Note that the release of the invariant-chain fragment from the binding groove of the class II MHC protein in the endosome is catalyzed by a class-II-MHC-like protein called HLA-DM. Viral glycoproteins can also be processed by this pathway for presentation to helper T cells. They are made in the ER, are transported to the plasma membrane, and can then enter endosomes after endocytosis.

Helper T Cells and Lymphocyte Activation

Helper T cells are arguably the most important cells in adaptive immunity, as they are required for almost all adaptive immune responses. They not only help activate B cells to secrete antibodies and macrophages to destroy ingested microbes, but they also help activate cytotoxic T cells to kill infected target cells. As dramatically demonstrated in AIDS patients, without helper T cells we cannot defend ourselves even against many microbes that are normally harmless.

Helper T cells themselves, however, can only function when activated to become effector cells. They are activated on the surface of antigen-presenting cells, which mature during the innate immune responses triggered by an infection. The innate responses also dictate what kind of effector cell a helper T cell will develop into and thereby determine the nature of the adaptive immune response elicited.

In this final section, we discuss the multiple signals that help activate a T cell and how a helper T cell, once activated to become an effector cell, helps activate other cells. We also consider how innate immune responses determine the nature of adaptive responses by stimulating helper T cells to differentiate into either T_H1 or T_H2 effector cells.

Costimulatory Proteins on Antigen-Presenting Cells Help Activate T Cells

To activate a cytotoxic or helper T cell to proliferate and differentiate into an effector cell, an antigen-presenting cell provides two kinds of signals. *Signal 1* is provided by a foreign peptide bound to an MHC protein on the surface of the presenting cell. This peptide-MHC complex signals through the T cell receptor and its associated proteins. *Signal 2* is provided by costimulatory proteins, especially the **B7 proteins** (CD80 and CD86), which are recognized by the co-receptor protein **CD28** on the surface of the T cell. The expression of B7 proteins on an antigen-presenting cell is induced by pathogens during the innate response to an infection. Effector T cells act back to promote the

expression of B7 proteins on antigen-presenting cells, creating a positive feedback loop that amplifies the T cell response.

Signal 2 is thought to amplify the intracellular signaling process triggered by signal 1. If a T cell receives signal 1 without signal 2, it may undergo apoptosis or become altered so that it can no longer be activated, even if it later receives both signals ([Figure 24-62](#)). This is one mechanism by which a T cell can become *tolerant* to self antigens.

The T cell receptor does not act on its own to transmit signal 1 into the cell. It is associated with a complex of invariant transmembrane proteins called **CD3**, which transduces the binding of the peptide-MHC complex into intracellular signals ([Figure 24-63](#)). In addition, the CD4 and CD8 co-receptors play important parts in the signaling process, as illustrated in [Figure 24-64](#).

The combined actions of signal 1 and signal 2 stimulate the T cell to proliferate and begin to differentiate into an effector cell by a curiously indirect mechanism. In culture, they cause the T cells to stimulate their own proliferation and differentiation by inducing the cells to secrete a cytokine called **interleukin-2 (IL-2)** and simultaneously to synthesize high affinity cell-surface receptors that bind it. The binding of IL-2 to the IL-2 receptors activates intracellular signaling pathways that turn on genes that help the T cells to proliferate and differentiate into effector cells ([Figure 24-65](#)). As discussed in [Chapter 15](#), there are advantages to such an autocrine mechanism. It helps ensure that T cells differentiate into effector cells only when substantial numbers of them respond to antigen simultaneously in the same location, such as in a lymph node during an infection. Only then do IL-2 levels rise high enough to be effective.

Once bound to the surface of an antigen-presenting cell, a T cell increases the strength of the binding by activating an integrin adhesion protein called *lymphocyte-function-associated protein 1 (LFA-1)*. Activated LFA-1 now binds more strongly to its Ig-like ligand, *intracellular adhesion molecule 1 (ICAM-1)*, on the surface of the presenting cell. This increased adhesion enables the T cell to remain bound to the antigen-presenting cell long enough for the T cell to become activated.

The activation of a T cell is controlled by negative feedback. During the activation process, the cell starts to express another cell-surface protein called *CTLA-4*, which acts to inhibit intracellular signaling. It resembles CD28, but it binds to B7 proteins on the surface of the antigen-presenting cell with much higher affinity than does CD28, and, when it does, it holds the activation process in check. Mice with a disrupted *CTLA-4* gene die from a massive accumulation of activated T cells.

Most of the T (and B) effector cells produced during an immune response must be eliminated after they have done their job. As antigen levels fall and the

response subsides, effector cells are deprived of the antigen and cytokine stimulation that they need to survive, and the majority die by apoptosis. Only memory cells and some long-lived effector cells survive.

Table 24-3 summarizes some of the co-receptors and other accessory proteins found on the surface of T cells.

Before considering how effector helper T cells help activate macrophages and B cells, we need to discuss the two functionally distinct subclasses of effector helper T cells, T_H1 and T_H2 cells, and how they are generated. [↑ TOP](#)

The Subclass of Effector Helper T Cell Determines the Nature of the Adaptive Immune Response

When a an antigen-presenting cell activates a naïve helper T cell in a peripheral lymphoid tissue, the T cell can differentiate into either a T_H1 or T_H2 effector helper cell. These two types of functionally distinct subclasses of effector helper T cells can be distinguished by the cytokines they secrete. If the cell differentiates into a **T_H1 cell**, it will secrete *interferon- γ* (*IFN- γ*) and *tumor*

necrosis factor- α (*TNF- α*) and will activate macrophages to kill microbes located within the macrophages' phagosomes. It will also activate cytotoxic T cells to kill infected cells. Although, in these ways, T_H1 cells mainly defend an animal against intracellular pathogens, they may also stimulate B cells to secrete specific subclasses of IgG antibodies that can coat extracellular microbes and activate complement.

If the naïve T helper cell differentiates into a **T_H2 cell**, by contrast, it will secrete *interleukins 4, 5, 10, and 13* (*IL-4, IL-5, IL-10, and IL-13*) and will mainly defend the animal against extracellular pathogens. A T_H2 cell can stimulate B cells to make most classes of antibodies, including IgE and some subclasses of IgG antibodies that bind to mast cells, basophils, and eosinophils. These cells release local mediators that cause sneezing, coughing, or diarrhea and help expel extracellular microbes and larger parasites from epithelial surfaces of the body.

Thus, the decision of naïve helper T cells to differentiate into T_H1 or T_H2 effector cells influences the type of adaptive immune response that will be mounted against the pathogen—whether it will be dominated by macrophage activation or by antibody production. The specific cytokines present during the process of helper T cell activation influence the type of effector cell produced. Microbes at a site of infection not only stimulate dendritic cells to make cell-surface B7 costimulatory proteins; they also stimulate them to produce cytokines. The dendritic cells then migrate to a peripheral lymphoid organ and

activate naïve helper T cells to differentiate into either T_H1 or T_H2 effector cells, depending on the cytokines the dendritic cells produce. Some intracellular bacteria, for example, stimulate dendritic cells to produce *IL-12*, which encourages T_H1 development, and thereby macrophage activation. As expected, mice that are deficient in either IL-12 or its receptor are much more susceptible to these bacterial infections than are normal mice. Many parasitic protozoa and worms, by contrast, stimulate the production of cytokines that encourage T_H2 development, and thereby antibody production and eosinophil activation, leading to parasite expulsion ([Figure 24-66](#)).

Once a T_H1 or T_H2 effector cell develops, it inhibits the differentiation of the other type of helper T cell. IFN- γ produced by T_H1 cells inhibits the development of T_H2 cells, while IL-4 and IL-10 produced by T_H2 cells inhibit the development of T_H1 cells. Thus, the initial choice of response is reinforced as the response proceeds.

The importance of the T_H1/T_H2 decision is illustrated by individuals infected with *Mycobacterium leprae*, the bacterium that causes leprosy. The bacterium replicates mainly within macrophages and causes either of two forms of disease, depending mainly on the genetic make-up of the infected individual. In some patients, the *tuberculoid* form of the disease occurs. T_H1 cells develop and stimulate the infected macrophages to kill the bacteria. This produces a local inflammatory response, which damages skin and nerves. The result is a chronic disease that progresses slowly but does not kill the host. In other patients, by contrast, the *lepromatous* form of the disease occurs. T_H2 cells develop and stimulate the production of antibodies. As the antibodies cannot get through the plasma membrane to attack the intracellular bacteria, the bacteria proliferate unchecked and eventually kill the host. [↑ TOP](#)

T_H1 Cells Help Activate Macrophages at Sites of Infection

T_H1 cells are preferentially induced by antigen-presenting cells that harbor microbes in intracellular vesicles. The bacteria that cause tuberculosis for example, replicate mainly in phagosomes inside macrophages, where they are protected from antibodies. They are also not readily attacked by cytotoxic T cells, which mainly recognize foreign antigens that are produced in the cytosol (see [Figure 24-58](#)). The bacteria can survive in phagosomes because they inhibit both the fusion of the phagosomes with lysosomes and the acidification of the phagosomes that is necessary to activate lysosomal hydrolases. Infected dendritic cells recruit helper T cells to assist in the killing of such microbes. The dendritic cells migrate to peripheral lymphoid organs, where they stimulate the production of T_H1 cells, which then migrate to sites of infection

to help activate infected macrophages to kill the microbes harboring in their phagosomes (see [Figure 24-66](#)).

T_H1 effector cells use two signals to activate a macrophage. They secrete IFN- γ , which binds to IFN- γ receptors on the macrophage surface, and they display the costimulatory protein **CD40 ligand**, which binds to **CD40** on the macrophage ([Figure 24-67](#)). (We see later that CD40 ligand is also used by helper T cells to activate B cells.) Once activated, the macrophage can kill the microbes it contains: lysosomes can now fuse more readily with the phagosomes, unleashing a hydrolytic attack, and the activated macrophage makes oxygen radicals and nitric oxide, both of which are highly toxic to the microbes (discussed in [Chapter 25](#)). Because dendritic cells also express CD40, the T_H1 cells at sites of infection can also help activate them. As a result, the dendritic cells increase their production of class II MHC proteins, B7 costimulatory proteins, and various cytokines, especially IL-12. This makes them more effective at stimulating helper T cells to differentiate into T_H1 effector cells in peripheral lymphoid organs, providing a positive feedback loop that increases the production of T_H1 cells and, thereby, the activation of macrophages.

T_H1 effector cells stimulate an inflammatory response by recruiting more phagocytic cells into the infected site. They do so in three ways:

1. They secrete cytokines that act on the bone marrow to increase the production of monocytes (macrophage precursors that circulate in the blood) and neutrophils.
2. They secrete other cytokines that activate endothelial cells lining local blood vessels to express cell adhesion molecules that cause monocytes and neutrophils in the blood to adhere there.
3. They secrete chemokines that direct the migration of the adherent monocytes and neutrophils out of the bloodstream into the site of infection.

T_H1 cells can also help activate cytotoxic T cells in peripheral lymphoid organs by stimulating dendritic cells to produce more costimulatory proteins. In addition, they can help effector cytotoxic T cells kill virus-infected target cells, by secreting IFN- γ , which increases the efficiency with which target cells process viral antigens for presentation to cytotoxic T cells (see [Figure 24-59](#)). An effector T_H1 cell can also directly kill some cells itself, including effector lymphocytes: by expressing *Fas ligand* on its surface, it can induce effector T or B cells that express cell-surface *Fas* to undergo apoptosis (see [Figure 24-46B](#)).

Both T_H1 and T_H2 cells can help stimulate B cells to proliferate and differentiate into either antibody-secreting effector cells or memory cells. They can also stimulate B cells to switch the class of antibody they make, from IgM (and IgD) to one of the secondary classes of antibody. Before considering how helper T cells do this, we need to discuss the role of the B cell antigen receptor in the activation of B cells. [↑ TOP](#)

Antigen Binding Provides Signal 1 to B Cells

Like T cells, B cells require two types of extracellular signals to become activated. Signal 1 is provided by antigen binding to the antigen receptor, which is a membrane-bound antibody molecule. Signal 2 is usually provided by a helper T cell. Like a T cell, if a B cell receives the first signal only, it is usually eliminated or functionally inactivated, which is one way in which B cells become tolerant to self antigens.

Signaling through the B cell antigen receptor works in much the same way as signaling through the T cell receptor (see [Figure 24-64](#)). The receptor is associated with two invariant protein chains, $Ig\alpha$ and $Ig\beta$, which help convert antigen binding to the receptor into intracellular signals. When antigen cross-links its receptors on the surface of a B cell, it causes the receptors and its associated invariant chains to cluster into small aggregates. This aggregation leads to the assembly of an intracellular signaling complex at the site of the clustered receptors and to the initiation of a phosphorylation cascade ([Figure 24-68](#)).

Just as the CD4 and CD8 co-receptors on T cells enhance the efficiency of signaling through the T cell receptor, so a co-receptor complex that binds complement proteins greatly enhances the efficiency of signaling through the B cell antigen receptor and its associated invariant chains. If a microbe activates the complement system (discussed in [Chapter 25](#)), complement proteins are often deposited on the microbe surface, greatly increasing the B cell response to the microbe. Now, when the microbe clusters antigen receptors on a B cell, the *complement-binding co-receptor complexes* are brought into the cluster, increasing the strength of signaling ([Figure 24-69A](#)). As expected, antibody responses are greatly reduced in mice lacking either one of the required complement components or complement receptors on B cells.

Later in the immune response, by contrast, when IgG antibodies decorate the surface of the microbe, a different co-receptor comes into play to dampen down the B cell response. These are *Fc receptors*, which bind the tails of the IgG antibodies. They recruit phosphatase enzymes into the signaling complex that decrease the strength of signaling ([Figure 24-69B](#)). In this way the Fc receptors on B cells act as inhibitory co-receptors, just as the CTLA-4 proteins do on T cells. Thus, the co-receptors on a T cell or B cell allow the cell to gain additional information about the antigen bound to its receptors and thereby

make a more informed decision as to how to respond.

Unlike T cell receptors, the antigen receptors on B cells do more than just bind antigen and transmit signal 1. They deliver the antigen to an endosomal compartment where the antigen is degraded to peptides, which are returned to the B cell surface bound to class II MHC proteins (see [Figure 24-60](#)). The peptide-class-II-MHC complexes are then recognized by effector helper T cells, which can now deliver signal 2. Signal 1 prepares the B cell for its interaction with a helper T cell by increasing the expression of both class II MHC proteins and receptors for signal 2. [↑ TOP](#)

Helper T Cells Provide Signal 2 to B Cells

Whereas antigen-presenting cells such as dendritic cells and macrophages are omnivorous and ingest and present antigens nonspecifically, a B cell generally presents only an antigen that it specifically recognizes. In a primary antibody response, naïve helper T cells are activated in a peripheral lymphoid organ by binding to a foreign peptide bound to a class II MHC protein on the surface of a dendritic cell. Once activated, the effector helper T cell can then activate a B cell that specifically displays the same complex of foreign peptide and class II MHC protein on its surface (see [Figure 24-66](#)).

The display of antigen on the B cell surface reflects the selectivity with which it takes up foreign proteins from the extracellular fluid. These foreign proteins are selected by the antigen receptors on the surface of the B cell and are ingested by receptor-mediated endocytosis. They are then degraded and recycled to the cell surface in the form of peptides bound to class II MHC proteins. Thus, the helper T cell activates those B cells with receptors that specifically recognize the antigen that initially activated the T cell, although the T and B cells usually recognize distinct antigenic determinants on the antigen (see [Figure 24-70](#)). In secondary antibody responses, memory B cells themselves can act as antigen-presenting cells and activate helper T cells, as well as being the subsequent targets of the effector helper T cells. The mutually reinforcing actions of helper T cells and B cells lead to an immune response that is both intense and highly specific.

Once a helper T cell has been activated to become an effector cell and contacts a B cell, the contact initiates an internal rearrangement of the helper cell cytoplasm. The T cell orients its centrosome and Golgi apparatus toward the B cell, as described previously for an effector cytotoxic T cell contacting its target cell (see [Figure 24-45](#)). In this case, however, the orientation is thought to enable the effector helper T cell to provide signal 2 by directing both membrane-bound and secreted signal molecules onto the B cell surface. The membrane-bound signal molecule is the transmembrane protein CD40 ligand, which we encountered earlier and is expressed on the surface of effector helper T cell, but not on nonactivated naïve or memory helper T cells. It is recognized by the CD40 protein on the B cell surface. The interaction between CD40

ligand and CD40 is required for helper T cells to activate B cells to proliferate and differentiate into memory or antibody-secreting effector cells. Individuals that lack CD40 ligand are severely immunodeficient. They are susceptible to the same infections that affect AIDS patients, whose helper T cells have been destroyed.

Secreted signals from helper T cells also help B cells to proliferate and differentiate and, in some cases, to switch the class of antibody they produce. *Interleukin-4 (IL-4)* is one such signal. Produced by T_H2 cells, it collaborates with CD40 ligand in stimulating B cell proliferation and differentiation, and it promotes switching to IgE antibody production. Mice deficient in IL-4 production are severely impaired in their ability to make IgE.

The signals required for T and B cell activation are compared in [Figure 24-70](#), and some of the cytokines discussed in this chapter are listed in [Table 24-4](#).

Some antigens can stimulate B cells to proliferate and differentiate into antibody-secreting effector cells without help from T cells. Most of these *T-cell-independent antigens* are microbial polysaccharides that do not activate helper T cells. Some activate B cells directly by providing both signal 1 and signal 2. Others are large polymers with repeating, identical antigenic determinants (see [Figure 24-29B](#)); their multipoint binding to B cell antigen receptors can generate a strong enough signal 1 to activate the B cell directly, without signal 2. Because T-cell-independent antigens do not activate helper T cells, they fail to induce B cell memory, affinity maturation, or class switching, all of which require help from T cells. They therefore mainly stimulate the production of low-affinity (but high-avidity) IgM antibodies. Most B cells that make antibodies without T cell help belong to a distinct B cell lineage. They are called *B1 cells* to distinguish them from *B2 cells*, which require T cell help. B1 cells seem to be especially important in defense against intestinal pathogens.  [TOP](#)

Immune Recognition Molecules Belong to an Ancient Superfamily

Most of the proteins that mediate cell-cell recognition or antigen recognition in the immune system contain Ig or Ig-like domains, suggesting that they have a common evolutionary history. Included in this [Ig superfamily](#) are antibodies, T cell receptors, MHC proteins, the CD4, CD8, and CD28 co-receptors, and most of the invariant polypeptide chains associated with B and T cell receptors, as well as the various Fc receptors on lymphocytes and other white blood cells. All of these proteins contain one or more Ig or Ig-like domains. In fact, about 40% of the 150 or so polypeptides that have been characterized on the surface of white blood cells belong to this superfamily. Many of these molecules are dimers or higher oligomers in which Ig or Ig-like domains of one chain interact with those in another ([Figure 24-71](#)).

The amino acids in each Ig-like domain are usually encoded by a separate exon. It seems likely that the entire gene superfamily evolved from a gene coding for a single Ig-like domain—similar to that encoding β_2 -microglobulin (see [Figure 24-50A](#)) or the Thy-1 protein (see [Figure 24-71](#))—that may have mediated cell-cell interactions. There is evidence that such a primordial gene arose before vertebrates diverged from their invertebrate ancestors about 400 million years ago. New family members presumably arose by exon and gene duplications.

The multiple gene segments that encode antibodies and T cell receptors may have arisen when a transposable element, or transposon (discussed in [Chapter 5](#)), inserted into an exon of a gene encoding an Ig family member in an ancestral lymphocyte-like cell. The transposon may have contained the ancestors of the *rag* genes, which, as discussed earlier, encode the proteins that initiate *V(D)J* joining; the finding that the RAG proteins can act as transposons in a test tube strongly supports this view. Once the transposon had inserted into the exon, the gene could be expressed only if the transposon was excised by the RAG proteins and the two ends of the exon were rejoined, much as occurs when the *V* and *J* gene segments of an Ig light chain gene are assembled (see [Figure 24-37](#)). A second insertion of the transposon into the same exon may then have divided the gene into three segments, equivalent to the present-day *V*, *D*, and *J* gene segments. Subsequent duplication of either the individual gene segments or the entire split gene may have generated the arrangements of gene segments that characterize the adaptive immune systems of present-day vertebrates.

Adaptive immune systems evolved to defend vertebrates against infection by pathogens. Pathogens, however, evolve more quickly, and they have acquired remarkably sophisticated strategies to counter these defenses, as we discuss in [Chapter 25](#). [↑ TOP](#)

Summary

Naïve T cells require at least two signals for activation. Both are provided by an antigen-presenting cell, which is usually a dendritic cell: signal 1 is provided by MHC-peptide complexes binding to T cell receptors, while signal 2 is mainly provided by B7 costimulatory proteins binding to CD28 on the T cell surface. If the T cell receives only signal 1, it is usually deleted or inactivated. When helper T cells are initially activated on a dendritic cell, they can differentiate into either T_H1 or T_H2 effector cells, depending on the cytokines in their environment: T_H1 cells activate macrophages, cytotoxic T cells, and B cells, while T_H2 cells mainly activate B cells. In both cases, the effector helper T cells recognize the same complex of foreign peptide and class II MHC protein on the target cell surface as they initially recognized on the dendritic cell that activated them. They activate their target cells by a

combination of membrane-bound and secreted signal proteins. The membrane-bound signal is CD40 ligand. Like T cells, B cells require two simultaneous signals for activation. Antigen binding to the B cell antigen receptors provides signal 1, while effector helper T cells provide signal 2 in the form of CD40 ligand and various cytokines.

Most of the proteins involved in cell-cell recognition and antigen recognition in the immune system, including antibodies, T cell receptors, and MHC proteins, as well as the various co-receptors discussed in this chapter, belong to the ancient Ig superfamily. This superfamily is thought to have evolved from a primordial gene encoding a single Ig-like domain. [↑ TOP](#)

Figure 24-62. The two signals that activate a helper T cell. (A) A mature antigen-presenting cell can deliver both signal 1 and 2 and thereby activate the T cell. (B) An immature antigen-presenting cell delivers signal 1 without signal 2, which can kill or inactivate the T cell; this is one mechanism for immunological tolerance to self antigens. One model for the role of signal 2 is that it induces the active transport of signaling proteins in the T cell plasma membrane to the site of contact between the T cell and the antigen-presenting cell. The accumulation of signaling proteins around the T cell receptor is thought to greatly enhance the intensity and duration of the signaling process activated by signal 1. In this way, "immunological synapses" form in the contact zone, with the T cell receptors (and their associated proteins—see [Figure 24-63](#)) and co-receptors in the center and cell-cell adhesion proteins forming a peripheral ring (not shown).

Figure 24-64. The signaling events initiated by the binding of peptide-MHC complexes to T cell receptors (signal 1). When T cell receptors are clustered by binding to peptide-MHC complexes on an antigen-presenting cell, CD4 molecules on helper cells or CD8 molecules on cytotoxic T cells are clustered with them, binding to invariant parts of the same class II or class I MHC proteins, respectively, on the presenting cell. This brings the Src-like cytoplasmic tyrosine kinase Lck into the signaling complex and activates it. Once activated, Lck phosphorylates tyrosines on the ζ and ϵ chains of the CD3 complex, which now serve as docking sites for yet another cytoplasmic tyrosine kinase called ZAP-70. Lck phosphorylates, and thereby activates, ZAP-70. Although not shown, ZAP-70 then phosphorylates tyrosines on the tail of another transmembrane protein, which then serve as docking sites for a variety of adaptor proteins and enzymes. These proteins then help relay the signal to the nucleus and other parts of the cell by activating the inositol phospholipid and MAP kinase signaling pathways (discussed in [Chapter 15](#)), as well as a Rho family GTPase that regulates the actin cytoskeleton (discussed in [Chapter 16](#)).

Figure 24-65. The stimulation of T cells by IL-2 in culture. Signals 1 and 2 activate T cells to make high affinity IL-2 receptors and to secrete IL-2. The binding of IL-2 to its receptors helps stimulate the cell to proliferate and differentiate into effector cells. Although some T cells do not make IL-2, as long as they have been activated by their antigen and therefore express IL-2 receptors, they can be helped to proliferate and differentiate by IL-2 made by neighboring T cells (not shown).

Figure 24-66. The activation of T_H1 and T_H2 cells. The differentiation of helper T cells into either T_H1 or T_H2 effector cells determines the nature of the subsequent adaptive immune responses that the effector cells activate. Whether a naïve helper T cell becomes a T_H1 or T_H2 cell depends mainly on the cytokines present when the helper T cell is activated by a mature dendritic cell in a peripheral lymphoid organ. The types of cytokines produced depend on the local environment and the nature of the microbe or parasite that activated the immature dendritic cell at the site of infection. IL-12 produced by mature dendritic cells promotes T_H1 cell development. The cytokine(s) produced by dendritic cells that promotes T_H2 cell development (cytokine X) is not known, although IL-4 produced by T cells can serve this function. In this figure, the effector T_H1 cell produced in the peripheral lymphoid organ migrates to the site of infection and helps a macrophage kill the microbes it has phagocytosed. The effector T_H2 cell remains in the lymphoid organ and helps activate a B cell to produce antibodies against the parasite. The antibodies arm mast cells, basophils, and eosinophils (not shown), which then can help expel the parasite from the gut.

Figure 24-68. Signaling events activated by the binding of antigen to B cell receptors (signal I). The antigen cross-links adjacent receptor proteins, which are transmembrane antibody molecules, causing the receptors and their associated invariant chains (Ig α and Ig β) to cluster. The Src-like tyrosine kinase associated with the cytosolic tail of Ig β joins the cluster and phosphorylates Ig α and Ig β (for simplicity, only the phosphorylation on Ig β is shown). The resulting phosphotyrosines on Ig α and Ig β serve as docking sites for another Src-like tyrosine kinase called Syk, which is homologous to ZAP-70 in T cells (see [Figure 24-64](#)). Like ZAP-70, Syk becomes phosphorylated and relays the signal downstream.

Figure 24-69. The influence of B cell co-receptors on the effectiveness of signal I. (A) The binding of microbe-complement complexes to a B cell cross-links the antigen receptors to complement-binding, co-receptor complexes. The cytosolic tail of one component of the co-receptor complex becomes phosphorylated on tyrosines, which then serve as docking sites for PI 3-kinase. As discussed in [Chapter 15](#), PI 3-kinase is activated to generate inositol phospholipid docking sites in the plasma membrane, which recruit intracellular signaling proteins (not shown). These signaling proteins act together with the signals generated by the Syk kinase to amplify the response. (B) When IgG antibodies become bound to foreign antigen, usually late in a response, the Fc regions of the antibodies bind to Fc receptors on the B cell surface and are thus recruited into the signaling complex. The Fc receptors become phosphorylated on tyrosines, which then serve as docking sites for an inositol phospholipid phosphatase. The phosphatase dephosphorylates the inositol phospholipid docking sites in the plasma membrane generated by PI 3-kinase, thereby reversing the activating effects of PI 3-kinase. The Fc receptors also inhibit signaling by recruiting protein tyrosine phosphatases into the signaling complex (not shown).

Figure 24-70. Comparison of the signals required to activate a helper T cell and a B cell. Note that in both cases secreted and membrane-bound molecules can cooperate to provide signal 2. Although not shown, CD40 is also expressed on the surface of mature dendritic cells and helps maintain helper T cells in an active state. The native protein antigen is endocytosed by both the dendritic cell and the B cell and is degraded in endosomes (not shown). The T cell antigenic determinant is presented on the surface of both the dendritic cell and the B cell as a peptide fragment bound to a class II MHC protein. By contrast, the B cell recognizes an antigenic determinant on the surface of the folded protein.

* CD stands for cluster of differentiation, as each of the CD proteins was originally defined as a blood cell "differentiation antigen" recognized by multiple monoclonal antibodies. Their identification depended on large-scale collaborative studies in which hundreds of such antibodies, generated in many laboratories, were compared and found to consist of relatively few groups (or "clusters"), each recognizing a single cell-surface protein. Since these initial studies, however, more than 150 CD proteins have been identified.

25. Pathogens, Infection, and Innate Immunity

Infectious and parasitic diseases currently cause about one third of all human deaths in the world, more than all forms of cancer combined. In addition to the continuing heavy burden of ancient diseases like tuberculosis and malaria, new infectious diseases are continually emerging, including the current pandemic (worldwide epidemic) of *AIDS (acquired immune deficiency syndrome)*, which has already caused more than twenty million deaths worldwide. Moreover, some diseases long thought to result from other causes are now turning out to be associated with infections. Most gastric ulcers, for example, are caused not by stress or spicy food, as was once believed, but by a bacterial infection of the stomach caused by *Helicobacter pylori*.

The burden of infectious and parasitic diseases is not spread equally across the planet. Poorer countries and communities suffer disproportionately. Frequently, there is a correlation between the prevalence of infectious diseases and poor public sanitation and public health systems, which are often further compromised by political upheavals. Some infectious diseases, however, occur primarily or exclusively among industrialized communities: Legionnaire's disease is a recent example.

Humans have long been troubled and fascinated with infectious diseases. The earliest written descriptions of how to limit the spread of rabies date back more than three thousand years. Since the mid-1800s, physicians and scientists have struggled to identify the agents that cause infectious diseases, collectively called pathogens. More recently, the advent of microbial genetics and molecular cell biology has greatly enhanced our understanding of the causes and mechanisms of infectious diseases. We now know that pathogens frequently exploit the biological attributes of their host's cells in order to infect them. This understanding can give us new insights into normal cell biology, as well as strategies for treating and preventing infectious diseases.

In a world teeming with hostile, clever, and rapidly evolving pathogens, how does a fragile and slowly evolving human survive? Like all other multicellular organisms, we have developed mechanisms to resist infection by pathogens. These defenses are of two kinds: innate immune responses, which spring into action immediately after an infection begins and do not depend on the host's

prior exposure to the pathogen, and adaptive immune responses, which are more powerful defenses that operate later in an infection and are highly specific for the pathogen that induced them.

In this chapter, we begin with an overview of the different kinds of organisms that cause disease. We then discuss the cell biology of infection and, finally, consider innate immunity. Adaptive immunity is the subject of Chapter 24.

Host–pathogen interactions. The bacterial pathogen *Listeria monocytogenes* grows directly in the cytoplasm of infected mammalian host cells, including the human cell shown here. These bacteria induce the assembly of comet-like tails of host cell actin filaments (*green*) that propel the invaders through the host cytoplasm and enable the infection to spread directly from a cell to its neighbors. Pathogens, Infection, and Innate Immunity

Introduction to Pathogens

We normally think of pathogens in hostile terms—as invaders that attack our bodies. But a pathogen or a parasite, like any other organism, is simply trying to live and procreate. Living at the expense of a host organism is a very attractive strategy, and it is possible that every living organism on earth is subject to some type of infection or parasitism ([Figure 25-1](#)). A human host is a nutrient-rich, warm, and moist environment, which remains at a uniform temperature and constantly renews itself. It is not surprising that many microorganisms have evolved the ability to survive and reproduce in this desirable niche. In this section, we discuss some of the common features that microorganisms must have in order to be infectious. We then explore the wide variety of organisms that are known to cause disease in humans.

Pathogens Have Evolved Specific Mechanisms for Interacting with Their Hosts

The human body is a complex and thriving ecosystem. It contains about 10^{13} human cells and also about 10^{14} bacterial, fungal, and protozoan cells, which represent thousands of microbial species. These microbes, called the **normal flora**, are usually limited to certain areas of the body, including the skin, mouth, large intestine, and vagina. In addition, humans are always infected with viruses, most of which rarely, if ever, become symptomatic. If it is normal for us to live in such close intimacy with a wide variety of microbes, how is it that some of them are capable of causing us illness or death?

Pathogens are usually distinct from the normal flora. Our normal microbial inhabitants only cause trouble if our immune systems are weakened or if they gain access to a normally sterile part of the body (for example, when a bowel perforation enables the gut flora to enter the peritoneal cavity of the abdomen, causing *peritonitis*). In contrast, dedicated pathogens do not require that the host be immunocompromised or injured. They have developed highly specialized mechanisms for crossing cellular and biochemical barriers and for eliciting specific responses from the host organism that contribute to the survival and multiplication of the pathogen.

 [Figure 25-16. Eradication of a viral disease...](#)

 [Figure 25-17. Neural degeneration in a prion...](#)

In order to survive and multiply in a host, a successful pathogen must be able to: (1) colonize the host; (2) find a nutritionally compatible niche in the host body; (3) avoid, subvert, or circumvent the host innate and adaptive immune responses; (4) replicate, using host resources; and (5) exit and spread to a new host. Under severe selective pressure to induce only the correct host cell responses to accomplish this complex set of tasks, pathogens have evolved mechanisms that maximally exploit the biology of their host organisms. Many of the pathogens we discuss in this chapter are skillful and practical cell biologists. We can learn a great deal of cell biology by observing them. [↑ TOP](#)

The Signs and Symptoms of Infection May Be Caused by the Pathogen or by the Host's Responses

Although we can easily understand why infectious microorganisms would evolve to reproduce in a host, it is less clear why they would evolve to cause disease. One explanation may be that, in some cases, the pathological responses elicited by microorganisms enhance the efficiency of their spread or propagation and hence clearly have a selective advantage for the pathogen. The virus-containing lesions on the genitalia caused by *herpes simplex* infection, for example, facilitate direct spread of the virus from an infected host to an uninfected partner during sexual contact. Similarly, diarrheal infections are efficiently spread from patient to caretaker. In many cases, however, the induction of disease has no apparent advantage for the pathogen.

Many of the symptoms and signs that we associate with infectious disease are direct manifestations of the host's immune responses in action. Some hallmarks of bacterial infection, including the swelling and redness at the site of infection and the production of pus (mainly dead white blood cells), are the direct result of immune system cells attempting to destroy the invading microorganisms. Fever, too, is a defensive response, as the increase in body temperature can inhibit the growth of some microorganisms. Thus, understanding the biology of an infectious disease requires an appreciation of the contributions of both pathogen and host. [↑ TOP](#)

Pathogens Are Phylogenetically Diverse

Many types of pathogens cause disease in humans. The most familiar are viruses and bacteria. Viruses cause diseases ranging from AIDS and smallpox to the common cold. They are essentially fragments of nucleic acid (DNA or RNA) instructions, wrapped in a protective shell of proteins and (in some cases) membrane ([Figure 25-2A](#)). They use the basic transcription and translation machinery of their host cells for their replication.

Of all the bacteria we encounter in our lives, only a small minority are dedicated pathogens. Much larger and more complex than viruses, bacteria are usually free-living cells, which perform most of their basic metabolic functions themselves, relying on the host primarily for nutrition ([Figure 25-2B](#)).

Some other infectious agents are eucaryotic organisms. These range from single-celled fungi and protozoa ([Figure 25-2C](#)), through large complex metazoa such as parasitic worms. One of the most common infectious diseases on the planet, shared by about a billion people at present, is an infestation in the gut by *Ascaris lumbricoides*. This nematode closely resembles its cousin *Caenorhabditis elegans*, which is widely used as a model organism for genetic and developmental biological research (discussed in [Chapter 21](#)). *C. elegans*, however, is only about 1 mm in length, whereas *Ascaris* can reach 30 cm ([Figure 25-2D](#)).

Some rare neurodegenerative diseases, including mad cow disease, are caused by an unusual type of infectious particle called a *prion*, which is made only of protein. Although the prion contains no genome, it can nevertheless replicate and kill the host.

Even within each class of pathogen, there is striking diversity. Viruses vary tremendously in their size, shape, and content (DNA versus RNA, enveloped or not, and so on), and the same is true for the other pathogens. The ability to cause disease (*pathogenesis*) is a lifestyle choice, not a legacy shared only among close relatives ([Figure 25-3](#)).

Each individual pathogen causes disease in a different way, which makes it challenging to understand the basic biology of infection. But, when considering the interactions of infectious agents with their hosts, some common themes of pathogenesis emerge. These common themes are the focus of this chapter. First, we introduce the basic features of each of the major types of pathogens that exploit features of host cell biology. Then, we examine in turn the mechanisms that pathogens use to control their hosts and the innate mechanisms that hosts use to control pathogens. [↑ TOP](#)

Bacterial Pathogens Carry Specialized Virulence Genes

Bacteria are small and structurally simple, compared to the vast majority of eucaryotic cells. Most can be classified broadly by their shape as rods, spheres, or spirals and by their cell-surface properties. Although they lack the elaborate morphological variety of eucaryotic cells, they display a surprising array of surface appendages that enable them to swim or to adhere to desirable surfaces ([Figure 25-4](#)). Their genomes are correspondingly simple, typically on the order of 1,000,000–5,000,000 nucleotide pairs in size (compared to 12,000,000 for yeast and more than 3,000,000,000 for humans).

As emphasized above, only a minority of bacterial species have developed the ability to cause disease in humans. Some of those that do cause disease can only replicate inside the cells of the human body and are called **obligate pathogens**. Others replicate in an environmental reservoir such as water or soil and only cause disease if they happen to encounter a susceptible host; these are

called **facultative pathogens**. Many bacteria are normally benign but have a latent ability to cause disease in an injured or immunocompromised host; these are called **opportunistic pathogens**.

Some bacterial pathogens are fastidious in their choice of host and will only infect a single species or a group of related species, whereas others are generalists. *Shigella flexneri*, for example, which causes epidemic dysentery (bloody diarrhea) in areas of the world lacking a clean water supply, will only infect humans and other primates. By contrast, the closely related bacterium *Salmonella enterica*, which is a common cause of food poisoning in humans, can also infect many other vertebrates, including chickens and turtles. A champion generalist is the opportunistic pathogen *Pseudomonas aeruginosa*, which is capable of causing disease in plants as well as animals.

The significant differences between a virulent pathogenic bacterium and its closest nonpathogenic relative may result from a very small number of genes. Genes that contribute to the ability of an organism to cause disease are called virulence genes. The proteins they encode are called **virulence factors**.

Virulence genes are frequently clustered together, either in groups on the bacterial chromosome called *pathogenicity islands* or on extrachromosomal *virulence plasmids* (Figure 25-5). These genes may also be carried on mobile *bacteriophages* (bacterial viruses). It seems therefore that a pathogen may arise when groups of virulence genes are transferred together into a previously avirulent bacterium. Consider, for example, *Vibrio cholerae*—the bacterium that causes cholera. Several of the genes encoding the toxins that cause the diarrhea in cholera are carried on a mobile bacteriophage (Figure 25-6). Of the hundreds of strains of *Vibrio cholerae* found in lakes in the wild, the only ones that cause human disease are those that have become infected with this virus.

Many virulence genes encode proteins that interact directly with host cells. Two of the genes carried by the *Vibrio cholerae* phage, for example, encode two subunits of **cholera toxin**. The B subunit of this secreted, toxic protein binds to a glycolipid component of the plasma membrane of the epithelial cells in the gut of a person who has consumed *Vibrio cholerae* in contaminated water. The B subunit transfers the A subunit through the membrane into the epithelial cell cytoplasm. The A subunit is an enzyme that catalyzes the transfer of an ADP-ribose moiety from NAD to the trimeric G protein G_s,

which normally activates adenylyl cyclase to make cyclic AMP (discussed in Chapter 15). ADP-ribosylation of the G protein results in an overaccumulation of cyclic AMP and an ion imbalance, leading to the massive watery diarrhea associated with cholera. The infection is then spread by the fecal-oral route by contaminated food and water.

Some pathogenic bacteria use several independent mechanisms to cause toxicity to the cells of their host. *Anthrax*, for example, is an acute infectious disease of sheep, cattle, other herbivores, and occasionally humans. It is usually caused by contact with spores of the Gram-positive bacterium, *Bacillus*

anthracis. Unlike cholera, anthrax has never been observed to spread directly from one infected person to another. Dormant spores can survive in soil for long periods of time and are highly resistant to adverse environmental conditions, including heat, ultraviolet and ionizing radiation, pressure, and chemical agents. After the spores are inhaled, ingested, or rubbed into breaks in the skin, the spores germinate, and the bacteria begin to replicate. Growing bacteria secrete two toxins, called **lethal toxin** and **edema toxin**. Either toxin alone is sufficient to cause signs of infection. Like the A and B subunits of cholera toxin, both toxins are made of two subunits. The B subunit is identical between lethal toxin and edema toxin, and it binds to a host cell-surface receptor to transfer the two different A subunits into host cells. The A subunit of edema toxin is an adenylyl cyclase that directly converts host cell ATP into cyclic AMP. This causes an ion imbalance that can lead to accumulation of extracellular fluid (*edema*) in the infected skin or lung. The A subunit of lethal toxin is a zinc protease that cleaves several members of the MAP kinase kinase family (discussed in [Chapter 15](#)). Injection of lethal toxin into the bloodstream of an animal causes shock and death. The molecular mechanisms and the sequence of events leading to death in anthrax remain uncertain.

These examples illustrate a common theme among virulence factors. They are frequently either toxic proteins (*toxins*) that directly interact with important host structural or signaling proteins to elicit a host cell response that is beneficial to pathogen colonization or replication, or they are proteins that are needed to deliver such toxins to their host cell targets. One common and particularly efficient delivery mechanism, called the type III secretion system, acts like a tiny syringe that injects toxic proteins from the cytoplasm of an extracellular bacterium directly into the cytoplasm of an adjacent host cell ([Figure 25-7](#)). There is a remarkable degree of structural similarity between the type III syringe and the base of a bacterial flagellum (see [Figure 15-67](#)), and many of the proteins in the two structures are clearly homologous.

Because bacteria form a kingdom distinct from the eucaryotes they infect (see [Figure 25-3](#)), much of their basic machinery for DNA replication, transcription, translation, and fundamental metabolism is quite different from that of their host. These differences enable us to find antibacterial drugs that specifically inhibit these processes in bacteria, without disrupting them in the host. Most of the antibiotics that we use to treat bacterial infections are small molecules that inhibit macromolecular synthesis in bacteria by targeting bacterial enzymes that are either distinct from their eucaryotic counterparts or that are involved in pathways, such as cell wall biosynthesis, that are absent in humans ([Figure 25-8](#) and [Table 6-3](#)). [↑ TOP](#)

Fungal and Protozoan Parasites Have Complex Life Cycles with Multiple Forms

Pathogenic fungi and protozoan parasites are eucaryotes. It is therefore more difficult to find drugs that will kill them without killing the host.

Consequently, antifungal and antiparasitic drugs are often less effective and more toxic than antibiotics. A second characteristic of fungal and parasitic infections that makes them difficult to treat is the tendency of the infecting organisms to switch among several different forms during their life cycles. A drug that is effective at killing one form is often ineffective at killing another form, which therefore survives the treatment.

The **fungal** branch of the eucaryotic kingdom includes both unicellular *yeasts* (such as *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe*) and filamentous, multicellular *molds* (like those found on moldy fruit or bread). Most of the important pathogenic fungi exhibit *dimorphism*—the ability to grow in either yeast or mold form. The yeast-to-mold or mold-to-yeast transition is frequently associated with infection. *Histoplasma capsulatum*, for example, grows as a mold at low temperature in the soil, but it switches to a yeast form when inhaled into the lung, where it can cause the disease histoplasmosis (Figure 25-9).

Protozoan parasites have more elaborate life cycles than do fungi. These cycles frequently require the services of more than one host. Malaria is the most common protozoal disease, infecting 200–300 million people every year and killing 1–3 million of them. It is caused by four species of *Plasmodium*, which are transmitted to humans by the bite of the female of any of 60 species of *Anopheles* mosquito. *Plasmodium falciparum*—the most intensively studied of the malaria-causing parasites—exists in no fewer than eight distinct forms, and it requires both the human and mosquito hosts to complete its sexual cycle (Figure 25-10). Gametes are formed in the bloodstream of infected humans, but they can only fuse to form a zygote in the gut of the mosquito. Three of the *Plasmodium* forms are highly specialized to invade and replicate in specific tissues—the insect gut lining, the human liver, and the human red blood cell.

Because malaria is so widespread and devastating, it has acted as a strong selective pressure on human populations in areas of the world that harbor the *Anopheles* mosquito. *Sickle cell anemia*, for example, is a recessive genetic disorder caused by a point mutation in the gene that encodes the hemoglobin β chain, and it is common in areas of Africa with a high incidence of the most serious form of malaria (caused by *Plasmodium falciparum*). The malarial parasites grow poorly in red blood cells from either homozygous sickle cell patients or healthy heterozygous carriers, and, as a result, malaria is seldom found among carriers of this mutation. For this reason, malaria has maintained the sickle cell mutation at high frequency in these regions of Africa.  [TOP](#)

Viruses Exploit Host Cell Machinery for All Aspects of Their Multiplication

Bacteria, fungi, and eucaryotic parasites are cells themselves. Even when they are obligate parasites, they use their own machinery for DNA replication, transcription, and translation, and they provide their own sources of metabolic

energy. **Viruses**, by contrast, are the ultimate hitchhikers, carrying little more than information in the form of nucleic acid. The information is largely replicated, packaged, and preserved by the host cells ([Figure 25-11](#)). Viruses have a small genome, made up of a single nucleic acid type—either DNA or RNA—which, in either case, may be single-stranded or double-stranded. The genome is packaged in a protein coat, which in some viruses is further enclosed by a lipid envelope.

Viruses replicate in various ways. In general, replication involves (1) disassembly of the infectious virus particle, (2) replication of the viral genome, (3) synthesis of the viral proteins by the host cell translation machinery, and (4) reassembly of these components into progeny virus particles. A single virus particle (a *virion*) that infects a single host cell can produce thousands of progeny in the infected cell. Such prodigious viral multiplication is often enough to kill the host cell: the infected cell breaks open (lyses) and thereby allows the progeny viruses access to nearby cells. Many of the clinical manifestations of viral infection reflect this *cytolytic effect* of the virus. Both the cold sores formed by *herpes simplex* virus and the lesions caused by the *smallpox* virus, for example, reflect the killing of the epidermal cells in a local area of infected skin.

Viruses come in a wide variety of shapes and sizes, and, unlike cellular life forms, they cannot be systematically classified by their relatedness into a single phylogenetic tree. Because of their tiny sizes, complete genome sequences have been obtained for nearly all clinically important viruses. *Poxviruses* are among the largest, up to 450 nm long, which is about the size of some small bacteria. Their genome of double-stranded DNA consists of about 270,000 nucleotide pairs. At the other end of the size scale are parvoviruses, which are less than 20 nm long and have a single-stranded DNA genome of under 5000 nucleotides ([Figure 25-12](#)). The genetic information in a virus can be carried in a variety of unusual nucleic acid forms ([Figure 25-13](#)).

The capsid that encloses the viral genome is made of one or several proteins, arranged in regularly repeating layers and patterns. In *enveloped viruses*, the capsid itself is enclosed by a lipid bilayer membrane that is acquired in the process of budding from the host cell plasma membrane ([Figure 25-14](#)). Whereas *nonenveloped viruses* usually leave an infected cell by lysing it, an enveloped virus can leave the cell by budding, without disrupting the plasma membrane and, therefore, without killing the cell. These viruses can cause chronic infections, and some can help transform an infected cell into a cancer cell.

Despite this variety, all viral genomes encode three types of proteins: proteins for replicating the genome, proteins for packaging the genome and delivering it to more host cells, and proteins that modify the structure or function of the host cell to suit the needs of the virus ([Figure 25-15](#)). In the second section of this chapter, we focus primarily on this third class of viral proteins.

Since most of the critical steps in viral replication are performed by host cell machinery, the identification of effective antiviral drugs is particularly problematic. Whereas the antibiotic tetracycline specifically poisons bacterial ribosomes, for example, it will not be possible to find a drug that specifically poisons viral ribosomes, as viruses use the ribosomes of the host cell to make their proteins. The best strategy for containing viral diseases is to prevent them by vaccination of the potential hosts. Highly successful vaccination programs have effectively eliminated smallpox from the planet, and the eradication of poliomyelitis is imminent ([Figure 25-16](#)). [↑ TOP](#)

Prions Are Infectious Proteins

All information in biological systems is encoded by structure. We are used to thinking of biological information in the form of nucleic acid sequences (as in our description of viral genomes), but the sequence itself is a shorthand code for describing nucleic acid structure. The replication and expression of the information encoded in DNA and RNA are strictly dependent on the structure of these nucleic acids and their interactions with other macromolecules. The propagation of genetic information primarily requires that the information be stored in a structure that can be duplicated from unstructured precursors. Nucleic acid sequences are the simplest and most robust solution that organisms have found to the problem of faithful structural replication.

Nucleic acids are not the only solution, however. Prions are infectious agents that are replicated in the host by copying an aberrant protein structure. They can occur in yeasts, and they cause various neurodegenerative diseases in mammals. The most well-known infection caused by prions is *bovine spongiform encephalopathy* (BSE, or mad cow disease), which occasionally spreads to humans who eat infected parts of the cow ([Figure 25-17](#)). Isolation of the infectious prions that cause the disease *scrapie* in sheep, followed by years of painstaking laboratory characterization of scrapie-infected mice, eventually established that the protein itself is infectious.

Intriguingly, the infectious prion protein is made by the host, and its amino acid sequence is identical to a normal host protein. Moreover, the prion and normal forms of the protein are indistinguishable in their posttranslational modifications. The only difference between them appears to be in their folded three-dimensional structure. The misfolded prion protein tends to aggregate, and it has the remarkable capacity to cause the normal protein to adopt its misfolded prion conformation and thereby to become infectious (see [Figure 6-89](#)). This ability of the prion to convert the normal host protein to misfolded prion protein is equivalent to the prion's having replicated itself in the host. If eaten by another susceptible host, these newly-misfolded prions can transmit the infection.

It is not known how normal proteins are usually able to find the single, correct, folded conformation, among the billions of other possibilities, without

becoming stuck in dead-end intermediates (discussed in [Chapters 3](#) and [6](#)). Prions are a good example of how protein folding can go dangerously wrong. But, why are the prion diseases so uncommon? What are the constraints that determine whether a misfolded protein will behave like a prion, or simply get refolded or degraded by the cell that made it? We do not yet have answers to these questions, and the study of prions remains an area of intense research. [↑ TOP](#)

Summary

Infectious diseases are caused by pathogens, which include bacteria, fungi, protozoa, worms, viruses, and even infectious proteins called prions. Pathogens of all classes must have mechanisms for entering their host and for evading immediate destruction by the host immune system. Most bacteria are not pathogenic. Those that are contain specific virulence genes that mediate interactions with the host, eliciting particular responses from the host cells that promote the replication and spread of the pathogen. Pathogenic fungi, protozoa, and other eucaryotic parasites typically pass through several different forms during the course of infection; the ability to switch among these forms is usually required for the parasites to be able to survive in a host and cause disease. In some cases, such as malaria, parasites must pass sequentially through several host species to complete their life cycles. Unlike bacteria and eucaryotic parasites, viruses have no metabolism of their own and no intrinsic ability to produce the proteins encoded by their DNA or RNA genomes. They rely entirely on subverting the machinery of the host cell to produce their proteins and to replicate their genomes. Prions, the smallest and simplest infectious agents, contain no nucleic acid; instead, they are rare, aberrantly folded proteins that happen to catalyze the misfolding of proteins in the host that share their primary amino acid sequence. Figure 25-1. Parasitism at many levels. (A) Scanning electron micrograph of a flea. The flea is a common parasite of mammals—including dogs, cats, rats, and humans. It drinks the blood of its host. Flea bites spread bubonic plague by passing the pathogenic bacterium *Yersinia pestis* from the bloodstream of one infected host to that of another. (B) A close-up view of a flea's leg reveals that this flea also has a parasite, a type of mite. The mite, in turn, is covered with bacteria. It is likely that these bacteria are parasitized by *bacteriophages*, which are bacterial viruses. A similar observation was reported by Jonathan Swift in 1733: So, naturalists observe, a flea Has smaller fleas that on him prey; And these have smaller still to bite 'em; And so proceed ad infinitum. (A, courtesy of Tina Carvalho/ MicroAngela; B, courtesy of Stanley Falkow.)

Figure 25-3. Phylogenetic diversity of pathogens. This diagram shows the similarities among 16S ribosomal RNA for cellular life forms (bacteria, archaea, and eucaryotes). Each branch is labeled with the name of a representative member of that group, and the length of the branches corresponds to the degree of difference in the rRNA sequence. Note that all the organisms we can see with the unaided eye (highlighted in yellow)—animals, plants, and fungi—represent a small subset of the diversity of life. In the two branches of the tree representing the bacteria and the eucaryotes, the branches that include known pathogens are indicated in red. No diseases are currently known to be caused by archaea, though many humans and all cows carry some types of archaea in their normal intestinal flora.

Figure 25-4. Bacterial shapes and cell-surface structures. Bacteria are classified into three different shapes: (A) spheres (cocci), (B) rods (bacilli), and (C) spiral cells (spirochetes). (D) They are also classified as *Gram-positive* or *Gram-negative*. Bacteria such as *Streptococci* and *Staphylococci* have a single membrane and a thick cell wall made of cross-linked *peptidoglycan*. They retain the violet dye used in the Gram staining procedure and are thus called Gram-positive. Gram-negative bacteria such as *E. coli* and *Salmonella* have two membranes, separated by a *periplasmic space* (see Figure 11-17). The peptidoglycan layer in the cell wall of these organisms is located in the periplasmic space and is thinner than in Gram-positives; they therefore fail to retain the dye in the Gram staining procedure. The inner membrane of Gram-negative bacteria is a

phospholipid bilayer, and the inner leaflet of the outer membrane is also made primarily of phospholipids; the outer leaflet of the outer membrane, however, is composed of a unique glycosylated lipid called *lipopolysaccharide (LPS)* (see [Figure 25-40](#)).

(E) Cell-surface projections are important for bacterial behavior. Many bacteria swim using the rotation of helical flagella (see [Figure 15-68](#)). The bacterium illustrated has only a single flagellum at one pole; others such as *E. coli* are decorated with multiple flagella all over the surface. Straight *pili* (also called *fimbriae*) are used to adhere to surfaces in the host and to facilitate genetic exchange between bacteria. Both flagella and pili are anchored to the cell surface by large multiprotein complexes.

Figure 25-5. Genetic differences between pathogens and nonpathogens.

Nonpathogenic *Escherichia coli* has a single circular chromosome. *E. coli* is very closely related to two types of food-borne pathogens — *Shigella flexneri*, which causes dysentery, and *Salmonella enterica*, a common cause of food poisoning. If these three organisms were being named today based on molecular techniques, they would be classified in the same genus, if not the same species. The chromosome of *S. flexneri* differs from that of *E. coli* at only a few loci; most of the genes required for pathogenesis are carried on an extrachromosomal virulence plasmid. The chromosome of *S. enterica* carries two large inserts (pathogenicity islands) not found in the *E. coli* chromosome; these inserts each contain many virulence genes.

Figure 25-6. Genetic organization of *Vibrio cholerae*. (A) *Vibrio cholerae* is unusual in having two circular chromosomes rather than one. The two chromosomes have distinct origins of replication ($oriC_1$ and $oriC_2$). Three loci

in pathogenic strains of *V. cholerae* are absent in nonpathogenic strains and appear to have been acquired relatively recently. CTX ϕ on chromosome 1 is an integrated bacteriophage genome that carries the genes for cholera toxin. The pathogenicity island VPI on chromosome 1 includes genes for factors required for intestinal colonization. The *integron island* on chromosome 2 is a structure that enables the sequential acquisition of novel genes by facilitating the insertion of newly acquired DNA fragments downstream of a strong transcriptional promoter. Although this integron island has not yet been shown to be required for virulence in *V. cholerae*, similar integron islands in many other pathogens contain virulence genes, as well as genes involved in antibiotic resistance. (B) Map of the CTX ϕ locus. The genes encoding the two subunits of cholera toxin are *ctxA* and *ctxB*. Other genes in the core region (*ace* and *zot*) are also involved in virulence. The two repeated flanking sequences RS2 and RS1 are involved in the chromosomal insertion of the bacteriophage genome.

Figure 25-15. A map of the HIV genome. This retroviral genome consists of about 9000 nucleotides and contains nine genes, the locations of which are shown in *green* and *red*. Three of the genes (*green*) are common to all retroviruses: *gag* encodes capsid proteins, *env* encodes envelope proteins, and *pol* encodes both the reverse transcriptase and the integrase proteins (discussed in [Chapter 5](#)). The HIV genome is unusually complex, because it contains six small genes (*red*), in addition to the three large genes (*green*) normally required for the retrovirus life cycle. At least some of these small genes encode proteins that regulate viral gene expression (*tat* and *rev*—see [Figure 7-97](#)); others encode proteins that modify host cell processes, including protein trafficking (*vpu* and *nef*) and progression through the cell cycle (*vpr*). As indicated by the *red* lines, RNA splicing (using the host cell spliceosome) is required to produce the Rev and Tat proteins.

Pathogens, Infection, and Innate Immunity

Cell Biology of Infection

We have just seen that pathogens constitute a diverse set of agents. There are correspondingly diverse ranges of mechanisms by which pathogens cause disease. But the survival and success of all pathogens require that they colonize the host, reach an appropriate niche, avoid host defenses, replicate, and exit the infected host to spread to an uninfected one. In this section, we examine the common strategies that are used by many pathogens to accomplish these tasks.

Pathogens Cross Protective Barriers to Colonize the Host

The first step in infection is for the pathogen to colonize the host. Most parts of the human body are well-protected from the environment by a thick and fairly tough covering of skin. The protective boundaries in some other human tissues (eyes, nasal passages and respiratory tract, mouth and digestive tract, urinary tract, and female genital tract) are less robust. For example, in the lungs and small intestine where oxygen and nutrients, respectively, are absorbed from the environment, the barrier is just a single monolayer of epithelial cells.

Skin and many other barrier epithelial surfaces are usually densely populated by normal flora. Some bacterial and fungal pathogens also colonize these surfaces and attempt to outcompete the normal flora, but most of them (as well as all viruses) avoid such competition by crossing these barriers to gain access to unoccupied niches within the host.

Wounds in barrier epithelia, including the skin, allow pathogens direct access to the interior of the host. This avenue of entry requires little in the way of specialization on the part of the pathogen. Indeed, many members of the normal flora can cause serious illness if they enter through such wounds. Anaerobic bacteria of the genus *Bacteroides*, for example, are carried as harmless flora at very high density in the large intestine, but they can cause life-threatening peritonitis if they enter the peritoneal cavity through a perforation in the intestine caused by trauma, surgery, or infection in the intestinal wall. *Staphylococcus* from the skin and nose, or *Streptococcus* from the throat and mouth, are also responsible for many serious infections resulting

from breaches in epithelial barriers.

Dedicated pathogens, however, need not wait for a well-timed wound to allow them access to their host. A particularly efficient way for a pathogen to cross the skin is to catch a ride in the saliva of a biting insect. Many arthropods nourish themselves by sucking blood, and a diverse group of bacteria, viruses, and protozoa have developed the ability to survive in the arthropod so that they can use these biting animals as *vectors* to spread from one mammalian host to another. As discussed earlier, the *Plasmodium* protozoan that causes malaria develops through several forms in its life cycle, including some that are specialized for survival in a human and some that are specialized for survival in a mosquito (see [Figure 25-10](#)). Viruses that are spread by insect bites include the causative agents for several types of hemorrhagic fever, including yellow fever and Dengue fever, as well as the causative agents for many kinds of viral encephalitis (inflammation of the brain). All these viruses have acquired the ability to replicate in both insect cells and mammalian cells, as is required for a virus to be transmitted by an insect vector. Bloodborne viruses such as HIV that are not capable of replicating in insect cells are rarely, if ever, spread from insect to human.

The efficient spread of a pathogen via an insect vector requires that individual insects consume blood meals from numerous mammalian hosts. In a few striking cases, the pathogen appears to alter the behavior of the insect so that its transmission is more likely. Like most animals, the tsetse fly (whose bite spreads the protozoan parasite *Trypanosoma brucei* which causes sleeping sickness in Africa) stops eating when it is satiated. But tsetse flies carrying trypanosomes bite much more frequently and ingest more blood than do uninfected flies. The presence of trypanosomes impairs the function of the insect mechanoreceptors that measure blood flow through the gullet to assess the fullness of the stomach, effectively fooling the tsetse fly into thinking that it is still hungry. The bacterium *Yersinia pestis*, which causes bubonic plague, uses a different mechanism to ensure that a flea carrying it bites repeatedly: it multiplies in the flea's foregut to form aggregated masses that eventually enlarge and physically block the digestive tract. The insect is then unable to feed normally and begins to starve. During repeated attempts to satisfy its appetite, some of the bacteria in the foregut are flushed into the bite site, thus transmitting plague to a new host ([Figure 25-18](#)). [↑ TOP](#)

Pathogens That Colonize Epithelia Must Avoid Clearance by the Host

Hitching a ride through the skin on an insect proboscis is just one strategy that pathogens use to pass through the initial barriers of host defense. Whereas many barrier zones such as the skin, mouth, and large intestine, are densely populated by normal flora, others including the lower lung, the small intestine, and the bladder, are normally kept nearly sterile, despite relatively direct access to the environment. The epithelium in these zones actively resists

bacterial colonization. As discussed in [Chapter 22](#), the respiratory epithelium is covered with a layer of protective mucus, and the coordinated beating of cilia sweeps the mucus and trapped bacteria and debris up and out of the lung. The epithelia lining the bladder and the upper gastrointestinal tract also have a thick layer of mucus, and these organs are periodically flushed by micturition and peristalsis, respectively, to wash away undesirable microbes. The pathogenic bacteria and parasites that infect these epithelial surfaces have specific mechanisms for overcoming these host cleaning mechanisms. Those that infect the urinary tract, for example, resist the washing action of urine by adhering tightly to the bladder epithelium via specific **adhesins**, proteins or protein complexes that recognize and bind to host cell-surface molecules. An important group of adhesins in uropathogenic *E. coli* strains are components of the *P pili* (see [Figure 25-4E](#)) that help the bacteria infect the kidney. These surface projections can be several micrometers long and are thus able to span the thickness of the protective mucus layer. At the tip of each pilus is a protein that binds tightly to a particular disaccharide linked to a glycolipid that is found on the surface of cells in the bladder and kidney ([Figure 25-19](#))

One of the hardest organs for a microbe to colonize is the stomach. Besides peristaltic washing and protection by a thick layer of mucus, the stomach is filled with acid (average pH ~2). This extreme environment is lethal to almost all bacteria ingested in food. Nonetheless, it is colonized by the hardy and enterprising bacterium *Helicobacter pylori*, which was recognized only recently as a major causative agent of stomach ulcers and possibly stomach cancer. Although the older treatments for ulcers (acid-reducing drugs and bland diets) are still used to reduce inflammation, a short and relatively cheap course of antibiotics can now effectively cure a patient of recurrent stomach ulcers. The hypothesis that stomach ulcers could be caused by a persistent bacterial infection of the stomach lining initially met with considerable skepticism. The point was finally proven by the young Australian doctor who made the initial discovery: he drank a flask of a pure culture of *H. pylori* and developed a typical ulcer. One way that *H. pylori* survives in the stomach is by producing the enzyme *urease*, which converts urea to ammonia and carbon dioxide; in this way, the bacterium surrounds itself with a layer of ammonia, which neutralizes stomach acid in its immediate vicinity. The bacteria also express at least five types of adhesins, which enable them to adhere to the stomach epithelium, and they produce several cytotoxins that destroy the stomach epithelial cells, creating painful ulcers. The resulting chronic inflammation promotes cell proliferation and thus predisposes the infected individual to stomach cancer.

A more extreme example of active colonization is provided by *Bordetella pertussis*, the bacterium that causes whooping cough. The first step in a *B. pertussis* infection is colonization of the respiratory epithelium. The bacteria circumvent the normal clearance mechanism (the *mucociliary escalator* described in [Chapter 22](#)) by binding tightly to the surface of ciliated cells and multiplying on them. *B. pertussis* expresses at least four types of adhesins that bind tightly to particular glycolipids on the ciliated cells. The adherent bacteria

produce various toxins which eventually kill the ciliated cells, compromising the host's ability to clear the infection. The most familiar of these is *pertussis toxin*, which—like cholera toxin—is an ADP-ribosylating enzyme. It ADP-ribosylates the α subunit of the G protein G_i , causing deregulation of the host cell adenylyl cyclase and overproduction of cyclic AMP (discussed in [Chapter 15](#)). Not content with this, *B. pertussis* also produces an adenylyl cyclase of its own, which is inactive unless bound to the eucaryotic Ca^{2+} -binding protein calmodulin. The bacterially-produced enzyme is therefore active only in the cytoplasm of a eucaryotic cell. Although both *B. pertussis* and *V. cholerae* have the similar effect of drastically raising cAMP levels in the host cells to which they adhere, the symptoms of the diseases are very different because the two bacteria colonize different sites in the host: *B. pertussis* colonizes the respiratory tract and causes paroxysmal coughing, whereas *V. cholerae* colonizes the gut and causes watery diarrhea.

Not all examples of specific colonization require that the bacterium express adhesins that bind to host cell glycolipids or proteins. Enteropathogenic *E. coli*, which causes diarrhea in young children, instead uses a type III secretion system (see [Figure 25-7](#)) to deliver its own bacterially-expressed receptor protein (called Tir) into its host cell ([Figure 25-20A](#)). After Tir is inserted into the host cell membrane, a bacterial surface protein binds to the extracellular domain of Tir, triggering a remarkable series of events inside the host cell. First, the Tir receptor protein is phosphorylated on tyrosine residues by a host protein tyrosine kinase. Unlike eucaryotic cells, bacteria generally do not phosphorylate tyrosine residues, yet Tir contains a peptide domain that is a specific recognition motif for a eucaryotic tyrosine kinase. The phosphorylated Tir then is thought to recruit a member of the Rho family of small GTPases, which promotes actin polymerization through a series of intermediate steps (discussed in [Chapter 16](#)). The polymerized actin forms a unique cell surface protrusion, called a *pedestal*, that pushes the tightly adherent bacteria up about 10 μm from the host cell surface ([Figure 25-20B, C](#)).

These examples of host colonization illustrate the importance of host-pathogen communication in the infection process. Pathogenic organisms have acquired genes that encode proteins that interact specifically with particular molecules of the host cells. In some cases, such as the *B. pertussis* adenylyl cyclase, an ancestor of the pathogen may have acquired the gene from its host, whereas in others, such as Tir, random mutation may have given rise to protein motifs that are recognized by a eucaryotic protein partner. [↑ TOP](#)

Intracellular Pathogens Have Mechanisms for Both Entering and Leaving Host Cells

Many pathogens, including *V. cholerae* and *B. pertussis*, infect their host without entering host cells. Others, however, including all viruses and many bacteria and protozoa, are **intracellular pathogens**. Their preferred niche for

replication and survival is within the cytoplasm or intracellular compartments of particular host cells. This strategy has several advantages. The pathogens are not accessible to *antibodies* (discussed in [Chapter 24](#)), and they are not easy targets for phagocytic cells (discussed below). This lifestyle, however, does require that the pathogen develop mechanisms for entering host cells, for finding a suitable subcellular niche where it can replicate, and for exiting the infected cell to spread the infection. In the remainder of this section, we consider some of the myriad ways that individual intracellular pathogens exploit and modify host cell biology to satisfy these requirements. [↑ TOP](#)

Viruses Bind to Molecules Displayed on the Host Cell Surface

The first step for any intracellular pathogen is to bind to the surface of the host target cell. For viruses, binding is accomplished through the association of a viral surface protein with a specific receptor on the host cell surface. Of course, no host cell receptor evolved for the sole purpose of allowing a pathogen to bind to it; these receptors all have other functions. The first such "virus receptor" identified was the *E. coli* surface protein that allows the bacteriophage lambda to bind to the bacterium. Its normal function is as a transport protein responsible for the uptake of maltose.

Viruses that infect animal cells generally use cell-surface receptor molecules that are either very abundant (such as sialic-acid-containing oligosaccharides, which are used by the influenza virus) or uniquely found on those cell types in which the virus can replicate (such as the nerve growth factor receptor, the nicotinic acetylcholine receptor, or the cell-cell adhesion protein N-CAM, all of which are used by the rabies virus to specifically infect neurons). Often, a single type of receptor is used by many types of virus, and some viruses can use several different receptors. Moreover, different viruses that infect the same cell type may each use a different receptor. Hepatitis, for example, is caused by at least six viruses, all of which preferentially replicate in liver cells. Receptors for four of the hepatitis viruses have been identified, and they are all different. Receptors need not be proteins; herpes simplex virus, for example, binds to heparan sulfate proteoglycans through specific viral membrane proteins.

Frequently, viruses require both a primary receptor and a secondary co-receptor for efficient attachment and entry into host cells. An important example is HIV. Its primary receptor is CD4, a protein involved in immune recognition which is found on the surface of many T cells and macrophages (discussed in [Chapter 24](#)). Viral entry also requires the presence of a co-receptor, either CCR5 (a receptor for β -chemokines) or CXCR4 (a receptor for α -chemokines), depending on the particular variant of the virus ([Figure 25-21](#)). Macrophages are susceptible only to HIV variants that use CCR5 for entry, whereas T cells are most efficiently infected by variants that use CXCR4. The viruses that are found within the first few months after HIV infection almost

invariably require CCR5, which presumably explains why individuals who carry a defective *ccr5* gene are not susceptible to HIV infection. In the later stages of infection, viruses may either switch to use the CXCR4 co-receptor or adapt to use both co-receptors; in this way, the virus can change the cell types it infects as the disease progresses. [↑ TOP](#)

Viruses Enter Host Cells by Membrane Fusion, Pore Formation, or Membrane Disruption

After recognition and attachment to the host cell surface, the virus must next enter the host cell and release its nucleic acid genome from its protective protein coat or lipid envelope. In most cases, the liberated nucleic acid remains complexed with some viral proteins. **Enveloped viruses** enter the host cell by fusing either with the plasma membrane or with the endosomal membrane following endocytosis ([Figure 25-22A,B](#)). Fusion is thought to proceed via a mechanism similar to SNARE-mediated fusion of vesicles during normal intracellular vesicular traffic (discussed in [Chapter 13](#)).

Fusion is regulated both to ensure that virus particles fuse only with the appropriate host cell membrane and to prevent virus particles from fusing with one another. For viruses such as HIV that fuse at neutral pH at the plasma membrane, binding to receptors or co-receptors usually triggers a conformational change in the viral envelope protein to expose a normally buried fusion peptide (see [Figure 13-16](#)). Other enveloped viruses, such as influenza, postpone fusion until after endocytosis; in this case, it is frequently the acid environment in the early endosome that triggers the conformational change in a viral surface protein that exposes the fusion peptide ([Figure 25-23](#)). The H⁺ pumped into the early endosome enters the influenza particle through an ion channel and triggers the *uncoating* of the viral nucleic acid, which is directly released into the cytosol as the virus fuses with the endosomal membrane. For some viruses, uncoating occurs after release into the cytosol. In the case of Semliki forest virus, for example, the binding of host ribosomes to the capsid causes the capsid proteins to separate from the viral genome.

It is more difficult to envision how **nonenveloped viruses** enter host cells, as it is not obvious how large assemblies of protein and nucleic acid can cross the plasma or endosomal membrane. Where the entry mechanism is understood, nonenveloped viruses generally either form a pore in the cell membrane to deliver the viral genome into the cytoplasm or they disrupt the endosomal membrane after endocytosis.

Poliovirus uses the first strategy. Binding of poliovirus to its receptor triggers both receptor-mediated endocytosis and a conformational change in the viral particle. The conformational change exposes a hydrophobic projection on one of the capsid proteins, which apparently inserts into the endosomal membrane to form a pore. The viral genome then enters the cytoplasm through the pore,

leaving the capsid either in the endosome or on the cell surface, or in both places (see [Figure 25-22C](#)).

Adenovirus uses the second strategy. It is initially taken up by receptor-mediated endocytosis. As the endosome matures and becomes more acidic, the virus undergoes multiple uncoating steps in which structural proteins are sequentially removed from the capsid. Some of these steps require the action of a viral protease, which is inactive in the extracellular virus particle (probably because of intrachain disulfide bonds) but which is activated in the reducing environment of the endosome. One of the proteins released from the capsid lyses the endosomal membrane, releasing the remainder of the virus into the cytosol. This trimmed-down virus then docks onto the nuclear pore complex, and the viral DNA genome is released through the pore into the nucleus, where it is transcribed (see [Figure 25-22D](#)).

In these various entry strategies, viruses exploit a variety of host cell molecules and processes, including cell-surface components, receptor-mediated endocytosis, and endosomal maturation steps. These strategies again illustrate the sophisticated ways that pathogens have evolved to utilize the basic cell biology of their hosts. [↑ TOP](#)

Bacteria Enter Host Cells by Phagocytosis

Bacteria are much larger than viruses, and they are too large to be taken up by receptor-mediated endocytosis. Instead, they enter host cells through phagocytosis. Phagocytosis of bacteria is a normal function of macrophages. They patrol the tissues of the body and ingest and destroy unwanted microbes. Some pathogens, however, have acquired the ability to survive and replicate within macrophages after they have been phagocytosed.

Tuberculosis, a serious lung infection that is widespread in some urban populations, is caused by one such pathogen, *Mycobacterium tuberculosis*. This bacterium is usually acquired by inhalation into the lungs, where it is phagocytosed by alveolar macrophages. Although the microbe can survive and replicate within macrophages, the macrophages of most healthy individuals, with the help of the adaptive immune system, contain the infection within a lesion called a *tubercle*. In most cases, the lesion becomes walled off within a fibrous capsule that undergoes calcification, after which it can easily be seen on an X-ray of the lungs of an infected person. An unusual feature of *M. tuberculosis* is its ability to survive for decades within macrophages contained in such lesions. Later in life, especially if the immune system becomes weakened by disease or drugs, the infection may be reactivated, spreading in the lung and even to other organs.

Tuberculosis has been an obvious presence in human populations for thousands of years, but another bacterium that lives within alveolar macrophages was first recognized as a human pathogen only in 1976.

Legionella pneumophila is normally a parasite of freshwater amoebae, which take it up by phagocytosis. When droplets of water containing *L. pneumophila* or infected amoebae are inhaled into the lung, the bacteria can invade and live inside alveolar macrophages (Figure 25-24), which, to the bacteria, must seem just like large amoebae. This infection leads to the type of pneumonia known as **Legionnaire's disease**. The pathogen can be efficiently spread by central air conditioning systems, as the amoebae that are the bacterium's normal host are particularly adept at growing in air-conditioning cooling towers; moreover, these cooling systems produce microdroplets of water that are easily inhaled. The incidence of Legionnaire's disease has increased dramatically in recent decades, and outbreaks are frequently traced to the air conditioning systems in office buildings, hospitals, and hotels. Other forms of modern aerosolization, including decorative fountains and produce sprayers in supermarkets, have also been implicated in outbreaks of this disease.

Some bacteria invade cells that are normally nonphagocytic. One way that bacteria can induce such a cell to phagocytose them is by expressing an adhesin that binds with high affinity to a cell adhesion protein that the cell normally uses to adhere to another cell or to the extracellular matrix (discussed in Chapter 19). For example, a bacterium that causes diarrhea, *Yersinia pseudotuberculosis* (a close relative of the plague bacterium *Yersinia pestis*), expresses a protein called *invasin* that binds to $\beta 1$ integrins, and *Listeria monocytogenes*, which causes a rare but serious form of food poisoning, expresses a protein that binds to E-cadherin. Binding to these transmembrane adhesion proteins fools the host cell into attempting to form a cell junction, and it begins moving actin and other cytoskeletal components to the site of bacterial attachment. Since the bacterium is small relative to the host cell, the host cell's attempt to spread over the adhesive surface of the bacterium results in the phagocytic uptake of the bacterium—a process known as the zipper mechanism of invasion (Figure 25-25A). The similarity of this form of invasion to the natural process of cell adhesion was underscored by the determination of the three-dimensional structure of *invasin*. This bacterial protein has an RGD motif, the structure of which is almost identical to that of the normal $\beta 1$ -integrin-binding site in laminin (discussed in Chapter 19).

A second pathway by which bacteria can invade nonphagocytic cells is known as the trigger mechanism (Figure 25-25B). It is used by various pathogens, including *Salmonella enterica*, which causes food poisoning. This dramatic form of invasion is initiated when the bacterium injects a set of effector molecules into the host cell cytoplasm through a type III secretion system. Some of these effector molecules activate Rho-family GTPases, which stimulate actin polymerization (discussed in Chapter 16). Others interact with cytoskeletal elements more directly, severing actin filaments and causing the rearrangement of cross-linking proteins. The net effect is to cause dramatic localized ruffling on the surface of the host cell (Figure 25-25C), which throws up large actin-rich protrusions that fold over and trap the bacterium within large endocytic vesicles called *macropinosomes*. The overall appearance of

cells being invaded by the trigger mechanism is similar to the dramatic ruffling induced by some growth factors, suggesting that similar intracellular signaling cascades are activated in both cases. [↑ TOP](#)

Intracellular Parasites Actively Invade Host Cells

The uptake of viruses by receptor-mediated endocytosis and bacteria by phagocytosis requires energy provided by the host cell. The pathogen is a relatively passive participant, usually providing a trigger to initiate the invasion process, but not contributing any metabolic energy. In contrast, the invasion of intracellular eucaryotic parasites, which are typically much larger than bacteria, proceeds through a variety of complex pathways that usually require significant energy expenditure on the part of the parasite.

Toxoplasma gondii, the cat parasite that also causes occasional serious human infections, is an instructive example. When this protozoan contacts a host cell, it protrudes a microtubule-ribbed structure called a *conoid* and then reorients so that the conoid is touching the host cell surface. The parasite then slowly pushes its way into the host cell. The energy for invasion seems to come entirely from the parasite, and the process can be disrupted by depolymerizing the parasite's—but not the host's—actin cytoskeleton. As the parasite moves into the host cell, it secretes lipids from a pair of specialized organelles, generating a vacuolar membrane that is made primarily of parasite lipids and proteins. In this way, the organism protects itself in a membrane-enclosed compartment within the host cell that does not participate in host cell membrane trafficking pathways and does not fuse with lysosomes ([Figure 25-26](#)). The specialized vacuolar membrane allows the parasite to take up metabolic intermediates and nutrients from the host cell cytosol but excludes larger molecules.

An entirely different, but no less peculiar, invasion strategy is used by the protozoan *Trypanosoma cruzi*, which causes a multiorgan disease (Chagas disease) mainly in Mexico and Central and South America. After attachment to $\beta 1$ integrins on the host cell surface, this parasite induces a local elevation of Ca^{2+} in the host cell cytoplasm. The Ca^{2+} signal recruits lysosomes to the site of parasite attachment, which then fuse with the plasma membrane, allowing the parasite to enter a vacuole derived almost entirely from lysosomal membrane ([Figure 25-27](#)). As we discuss below, most intracellular pathogens go to great lengths to avoid exposure to the hostile, proteolytic environment of the lysosome, but this trypanosome uses the lysosome as its means of entry. In the vacuole, the parasite secretes a transsialidase enzyme that removes sialic acid from lysosomal glycoproteins and transfers it to its own surface molecules, thereby coating itself with host cell sugars. Next, the parasite secretes a pore-forming toxin that lyses the vacuolar membrane, releasing the parasite into the host cell cytosol, where it replicates. [↑ TOP](#)

Many Pathogens Alter Membrane Traffic in the Host Cell

The two examples of intracellular parasites discussed in the preceding section raise a general problem that faces all pathogens with an intracellular lifestyle, including viruses, bacteria, and parasites. They must deal in some way with membrane traffic in the host cell. After endocytosis by a host cell, they usually find themselves in an endosomal compartment that normally would fuse with lysosomes. They therefore must either modify the compartment to prevent its fusion, escape from the compartment before getting digested, or find ways to survive in the hostile environment of the phagolysosome ([Figure 25-28](#)).

Most pathogens use either the first or second strategy. It is much less common to find pathogens that can survive in the phagolysosome. As we have seen, *Trypanosoma cruzi* uses the escape route, as do essentially all viruses (see [Figure 25-22](#)). The bacterium *Listeria monocytogenes* also uses this strategy. It is taken up into cells via the zipper mechanism discussed earlier and secretes a protein called *hemolysin* that forms large pores in the phagosomal membrane, eventually disrupting the membrane and releasing the bacteria into the cytosol. Once in the cytosol, the bacteria continue to secrete hemolysin, but it does not destroy the plasma membrane. The hemolysin selectively destroys only the phagosomal membrane for two reasons: first, it is ten times more active at the acidic pH found in the phagosome than at neutral pH found in the cytosol, and second, the hemolysin contains a PEST sequence (a peptide motif rich in proline, glutamate, serine, and threonine), which is recognized by the protein degradation machinery of the host cell, leading to the rapid degradation of the bacterial hemolysin in the proteasome (see [Figure 6-86](#)). The hemolysin is stable in the phagosome, as the degradation machinery does not have access to it there ([Figure 25-29](#)). The hemolysin secreted by *L. monocytogenes* is closely related to hemolysins secreted by other bacteria that are not intracellular pathogens. These related hemolysins, however, all lack PEST sequences. It seems that the *L. monocytogenes* hemolysin has acquired an essentially eucaryotic protein domain expressly to allow its activity to be regulated in the host cell.

By far the most common strategy used by intracellular bacteria and parasites is to modify the endosomal compartment so that they can remain there and replicate. They must modify the compartment in at least two ways: first, they must prevent lysosomal fusion, and second, they must provide a pathway for importing nutrients from the host cytosol. Different pathogens have distinct strategies for doing this. As we have seen, *Toxoplasma gondii* creates its own membrane-enclosed compartment that does not participate in normal host cell membrane traffic and allows nutrient transport. This option is not open to bacteria, which are too small to carry in their own supply of membrane. *Mycobacterium tuberculosis* somehow prevents the very early endosome that contains it from maturing, so that it never acidifies or acquires the characteristics of a late endosome. Endosomes containing *Salmonella enterica*, in contrast, do acidify and acquire markers of late endosomes, but they arrest their maturation at a stage prior to lysosomal fusion. Other bacteria seem to find shelter in intracellular compartments that are completely distinct from the

usual endocytic pathway. *Legionella pneumophila*, for example, replicates in compartments that are wrapped in layers of rough endoplasmic reticulum. *Chlamydia trachomatis*, a sexually transmitted bacterial pathogen that can cause sterility and blindness, replicates in a compartment that seems to be most similar to part of the exocytic pathway (Figure 25-30). The mechanisms used by these organisms to alter their membrane compartments are not yet understood.

Viruses also often alter membrane traffic in the host cell. Enveloped viruses must acquire their membrane from host cell phospholipids. In the simplest cases, virally encoded proteins are inserted into the ER membrane and follow the usual path through the Golgi apparatus to the plasma membrane, undergoing various posttranslational modifications *en route*. The viral capsid then assembles at the plasma membrane and buds off from the cell surface. This is the mechanism used by HIV. Other enveloped viruses interact in complex ways with membrane trafficking pathways in the host cell (Figure 25-31). Even some nonenveloped viruses alter membrane traffic in the host cell to suit their own purposes. The replication of poliovirus, for example, is carried out by a membrane-associated, virus-encoded RNA polymerase. Replication can proceed more quickly if the surface area of the host cell membranes is increased. To accomplish this, the virus induces increased lipid synthesis in the host cell and blocks secretion from the ER. Intracellular membranes thereby accumulate, expanding the surface area on which RNA replication can occur (Figure 25-32).  [TOP](#)

Viruses and Bacteria Exploit the Host Cell Cytoskeleton for Intracellular Movement

The cytoplasm of mammalian cells is extremely viscous. It is crowded with organelles and supported by networks of cytoskeletal filaments, all of which inhibit the diffusion of particles the size of a bacterium or a viral capsid. If a pathogen must reach a particular part of the cell to carry out part of its replication cycle, it must move there actively. As with transport of intracellular organelles, pathogens generally use the cytoskeleton for active movement.

Several bacteria that replicate in the host cell cytosol (rather than in membrane-enclosed compartments) have adopted a remarkable mechanism for moving, which depends on actin polymerization. These bacteria, including *Listeria monocytogenes*, *Shigella flexneri*, and *Rickettsia rickettsii* (which causes Rocky Mountain spotted fever) induce the nucleation and assembly of host cell actin filaments at one pole of the bacterium. The growing filaments generate substantial force and push the bacteria through the cytoplasm at rates up to 1 $\mu\text{m}/\text{sec}$. New filaments form at the rear of each bacterium and are left behind like a rocket trail as the bacterium advances, depolymerizing again within a minute or so as they encounter depolymerizing factors in the cytosol. When a moving bacterium reaches the plasma membrane, it continues to move outward, inducing the formation of a long, thin protrusion with the bacterium

at its tip. This projection is often engulfed by a neighboring cell, allowing the bacterium to enter the neighbor's cytoplasm without exposure to the extracellular environment, thereby avoiding recognition by antibodies produced by the host's adaptive immune system ([Figure 25-33](#)).

The molecular mechanism of pathogen-induced actin assembly has been determined for two of these bacteria. The mechanisms are different, suggesting that they evolved independently. Although both make use of the same host cell regulatory pathway that normally controls the nucleation of actin filaments, they exploit different points in the pathway. As discussed in [Chapter 16](#), activation of the small GTPase Cdc42 by growth factors or other external signals causes the activation of a protein called N-WASp, which in turn activates the ARP complex that can nucleate the growth of a new actin filament. An *L. monocytogenes* surface protein directly binds to and activates the ARP complex to initiate the formation of an actin tail, while an unrelated surface protein on *S. flexneri* binds to and activates N-WASp, which then activates the ARP complex. Remarkably, vaccinia virus uses yet another mechanism to move intracellularly by inducing actin polymerization, again exploiting this same regulatory pathway ([Figure 25-34](#)).

Other pathogens rely primarily on microtubule-based transport to move within the host cell. This movement is particularly well-illustrated by viruses that infect neurons. An important example is provided by the neurotropic alpha herpes viruses, a group that includes the virus that causes chicken pox. Upon infection of sensory neurons, the virus particles are transported to the nucleus by microtubule-based transport, probably mediated by attachment of the capsids to the motor protein dynein. After replication and assembly in the nucleus, the enveloped virus is transported along microtubules away from the neuronal cell body down the axon, presumably by attachment to a kinesin motor protein ([Figure 25-35](#)).

One bacterium that is known to associate with microtubules is *Wolbachia*. This fascinating genus includes many species that are parasites or symbionts of insects and other invertebrates, living in the cytosol of each cell in the animal. The infection is spread vertically from mother to offspring, as *Wolbachia* are also present in eggs. The bacteria ensure their transmission into every cell by binding to microtubules, and they are therefore segregated by the mitotic spindle simultaneously with chromosome segregation when an infected cell divides ([Figure 25-36](#)). As we discuss later, *Wolbachia* infection can significantly alter the reproductive behavior of its insect hosts. [↑ TOP](#)

Viruses Take Over the Metabolism of the Host Cell

Most intracellular bacteria and parasites carry the basic genetic information required for their own metabolism and replication, and they rely on their host cells only for nutrients. Viruses, in contrast, use the basic host cell machinery for most aspects of their reproduction: they all depend on host cell ribosomes

to produce their proteins, and some also use host cell DNA and RNA polymerases for replication and transcription, respectively.

Many viruses encode proteins that modify the host transcription or translation apparatus to favor the synthesis of viral proteins over those of the host cell. As a result, the synthetic capability of the host cell is directed principally to the production of new virus particles. Poliovirus, for example, encodes a protease that specifically cleaves the TATA-binding factor component of TFIID (see [Figure 6-16](#)), effectively shutting off all host cell transcription via RNA polymerase II. Influenza virus produces a protein that blocks both the splicing and the polyadenylation of mRNA transcripts, which therefore fail to be exported from the nucleus (see [Figure 6-40](#)).

Translation initiation of most host cell mRNAs depends on recognition of their 5' cap by a group of translation initiation factors (see [Figure 6-71](#)). Translation initiation of host mRNAs is often inhibited during viral infection, so that the host cell ribosomes can be used more efficiently for synthesis of viral proteins. Some viruses encode endonucleases that cleave the 5' cap from host cell mRNAs. Some even then use the liberated 5' caps as primers to synthesize viral mRNAs, a process called *cap snatching*. Several other viral RNA genomes encode proteases that cleave certain translation initiation factors. These viruses rely on 5' cap-independent translation of the viral RNA, using internal ribosome entry sites (IRESs) (see [Figure 7-102](#)).

A few DNA viruses use host cell DNA polymerase to replicate their genome. These viruses need to solve a problem: DNA polymerase is expressed at high levels only during S phase of the cell cycle, whereas most cells that the viruses infect spend most of their time in G₁ phase. Adenovirus solves this problem by inducing the host cell to enter S phase. Its genome encodes proteins that inactivate both Rb and p53, two key suppressors of cell-cycle progression (discussed in [Chapter 17](#)). As might be expected for any mechanism that induces unregulated DNA replication, these viruses are frequently oncogenic. [↑ TOP](#)

Pathogens Can Alter the Behavior of the Host Organism to Facilitate the Spread of the Pathogen

As we have seen, pathogens often alter the behavior of the host cell in ways that benefit the survival and replication of the pathogen. Similarly, pathogens often alter the behavior of the whole host organism to facilitate pathogen spread, as we saw earlier for *Trypanosoma brucei* and *Yersinia pestis*. In some cases, it is difficult to tell whether a particular host response is more for the benefit of the host or for the pathogen. Pathogens like *Salmonella enterica* that cause diarrhea, for example, usually produce self-limiting infections because the diarrhea efficiently washes out the pathogen. The bacteria-laden diarrhea,

however, can spread the infection to a new host. Similarly, coughing and sneezing help to clear patho-gens from the respiratory tract, but they also spread the infection to new individuals. A person with a common cold may produce 20,000 droplets in a single sneeze, all carrying rhinovirus or corona virus.

A frightening example of a pathogen modifying host behavior is seen in rabies, as first described in Egyptian writings over 3000 years ago. This virus replicates in neurons and causes infected people or animals to become "rabid": they are unusually aggressive and develop a strong desire to bite. The virus is shed in the saliva and transmitted through the bite wound into the bloodstream of the victim, spreading the infection to a new host.

Toxoplasma gondii, a eucaryotic parasite that forms lesions in muscle and brain tissue, provides an equally remarkable example. It can complete its life cycle only in its normal host—cats. If it infects an intermediate host, such as a rodent or human, the infection is a dead end for the parasite, unless the intermediate host is eaten by a cat. Behavioral studies show that rats infected with *T. gondii* lose their innate fear of cats and instead preferentially seek out locations perfumed with cat urine over locations perfumed with rabbit urine, exactly the opposite of normal rat behavior.

But the most dramatic example of pathogens modifying host behavior belongs to *Wolbachia*. These bacteria manipulate the sexual behavior of their host to maximize their dissemination. As described earlier, *Wolbachia* are passed vertically into offspring through eggs. If they live in a male, however, they hit a dead end, as they are excluded from sperm. In some species of *Drosophila*, *Wolbachia* modify the sperm of their host so that they can fertilize the eggs only of infected females. This modification creates a reproductive advantage for infected females over uninfected females, so that the overall proportion of *Wolbachia* carriers increases. In other host species, a *Wolbachia* infection kills males but spares females, increasing the number of females in the population and thus the number of individuals that can produce eggs to pass on the infection. In a few types of wasp, *Wolbachia* infections enable the females to produce eggs that develop parthenogenetically without the need for fertilization by sperm; in this species, males have been completely eliminated. For some of its hosts, *Wolbachia* has become an indispensable symbiont, and curing the infection causes death of the host. In one case, humans are making use of this dependence: the filarial nematode that causes African river blindness is difficult to kill with antiparasite medications, but when people with river blindness are treated with antibiotics that cure the nematode's *Wolbachia* infection, the nematode infection is also arrested.  [TOP](#)

Pathogens Evolve Rapidly

The complexity and specificity of the molecular interactions between pathogens and their host cells might suggest that virulence would be difficult to acquire by random mutation. Yet, new pathogens are constantly emerging,

and old pathogens are constantly changing in ways that make familiar infections difficult to treat. Pathogens have two great advantages that enable them to evolve rapidly. First, they replicate very quickly, providing a great deal of material for the engine of natural selection. Whereas humans and chimpanzees have acquired a 2% difference in genome sequences over about 8 million years of divergent evolution, poliovirus manages a 2% change in its genome in 5 days, about the time it takes the virus to pass from the human mouth to the gut. Second, this rapid genetic variation is acted on by powerful selective pressures provided by the host's adaptive immune system and by modern medicine, which destroy pathogens that fail to change.

A small-scale example of the constant battle between infection and immunity is the phenomenon of antigenic variation. An important adaptive immune response against many pathogens is the production of antibodies that recognize specific antigens on the pathogen surface (discussed in Chapter 24). Many pathogens evade complete elimination by antibodies by changing these antigens during the course of an infection. Some parasites, for example, undergo programmed rearrangements of the genes encoding their surface antigens. The most striking example occurs in African trypanosomes such as *Trypanosoma brucei*, a parasite that causes sleeping sickness and is spread by an insect vector (*T. brucei* is a close relative of *T. cruzi* (see Figure 25-27), but it replicates extracellularly rather than inside cells). *T. brucei* is covered with a single type of glycoprotein, called *variant-specific glycoprotein* (VSG), which elicits a protective antibody response that rapidly clears most of the parasites. The trypanosome genome, however, contains about 1000 VSG genes, each encoding a VSG with distinct antigenic properties. Only one of these genes is expressed at any one time, by being copied into an active expression site in the genome. The VSG gene expressed can be changed repeatedly by gene rearrangements that copy new alleles into the expression site. In this way, a few trypanosomes with an altered VSG escape the antibody-mediated clearance, replicate, and cause a recurrence of disease, leading to a chronic cyclic infection (Figure 25-37).

A different type of antigenic variation occurs during the course of infection by viruses that have error-prone replication mechanisms. Retroviruses, for example, acquire on average one point mutation every replication cycle, because the viral reverse transcriptase that produces DNA from the viral RNA genome cannot correct nucleotide misincorporation errors. A typical, untreated HIV infection may eventually involve HIV genomes with every possible point mutation. In some ways, the high mutation rate is beneficial for the pathogen. By a microevolutionary process of mutation and selection within each host, the virus can switch from infecting macrophages to infecting T-cells (as described earlier), and, once treatment is begun, it can quickly acquire resistance to drugs. If the reverse transcriptase error rate were too high, however, deleterious mutations might accumulate too rapidly to allow the virus to survive. Furthermore, rapid viral diversification in one host does not necessarily lead to rapid evolution of the virus in the population, as a mutated virus may not be able to infect a new host. For HIV-1, the extent of this

constraint can be estimated by examining the sequence diversity among different individuals infected with the virus. Remarkably, only about one-third of the nucleotide positions in the coding sequence of the virus are invariant, and nucleotide sequences in some parts of the genome, such as the *env* gene, can differ by as much as 30%. This extraordinary genomic plasticity greatly complicates attempts to develop vaccines against HIV, and it can also lead to rapid drug resistance (see below). A further consequence has been rapid diversification and emergence of new HIV strains. Sequence comparisons between various strains of HIV and the very similar simian immunodeficiency virus (SIV) from a variety of different monkey species seem to indicate that the most virulent type of HIV, HIV-1, may have jumped from chimpanzees to humans as recently as 1930 (Figure 25-38).

Rapid evolution in bacteria frequently takes place by horizontal gene transfer rather than by point mutation. Most of this horizontal gene transfer is mediated by the acquisition of plasmids and bacteriophages. Bacteria readily pick up pathogenicity islands and virulence plasmids (see Figure 25-5) from other bacteria. Once a bacterium has acquired a new set of virulence-related genes, it may quickly establish itself as a new cause of human epidemics. *Yersinia pestis*, for example, is an infection endemic to rats and other rodents that first appeared in human history in 542 A.D., when the city of Constantinople was devastated by plague. Sequence comparisons of *Y. pestis* to its close relative *Y. pseudotuberculosis*, which causes a severe diarrheal disease, suggest that *Y. pestis* may have emerged as a distinct strain only a few thousand years ago, not long before its debut in the field of urban devastation.

The emergence and evolution of new infectious disease is in many cases exacerbated by changes in human behavior. For example, crowded and filthy living conditions in medieval cities contributed to the spread of plague to humans from the natural rodent host. The tendency of modern humans to live at high population densities in large cities has also created the opportunity for infectious organisms to initiate epidemics, such as influenza, tuberculosis, and AIDS, which could not have spread so rapidly or so far among sparser human populations. Air travel can, in principle, allow an asymptomatic, newly infected host to carry an epidemic to any previously unexposed population within a few hours or days. Modern agricultural practices also foster the emergence of certain types of infectious agents that could not have easily developed in the hunter-gatherer societies of early humans. Influenza viruses, for example, are unusual in that their genome consists of several (usually eight) strands of RNA. When two strains of influenza infect the same host, the strands of the two strains can reshuffle to form a new and distinct type of influenza virus. Prior to 1900, the influenza strain that infected humans caused a very mild disease; a separate influenza strain infected fowl such as ducks and chickens but could not infect humans. Both the avian and the human strains, however, are capable of infecting pigs, and can recombine in a pig host to form new strains that can cause serious human disease. In communities where pigs are farmed together with chickens or turkeys, newly recombined influenza strains periodically emerge and cause worldwide epidemics. The first and most

serious of these epidemics was the "Spanish flu" epidemic of 1918, which killed more people than did World War I. [↑ TOP](#)

Drug Resistant Pathogens Are a Growing Problem

While some human activities have promoted the spread of certain infectious diseases, advances in public sanitation and in medicine have prevented or alleviated the suffering caused by many others. Effective vaccines and worldwide vaccination programs have eliminated smallpox and severely reduced poliomyelitis, and many deadly childhood infections such as mumps and measles are now rarities in wealthy industrialized nations. However, there are still many widespread and devastating infectious diseases, such as malaria, for which no effective vaccines are available. Of equal importance is the development of drugs that cure rather than prevent infections. The most successful class are the *antibiotics*, which kill bacteria. Penicillin was one of the first antibiotics used to treat infections in humans, introduced into clinical use just in time to prevent tens of thousands of deaths from infected battlefield wounds in World War II. The rapid evolution of pathogens, however, has enabled targeted bacteria to develop resistance to antibiotics very quickly; the typical lag between introduction of an antibiotic into clinical use and the appearance of resistant strains is only a few years. Similar drug resistance arises rapidly among viruses when infections are treated with antiviral agents. The virus population in an HIV-infected person treated with the reverse transcriptase inhibitor AZT, for example, will acquire complete resistance to the drug within a few months. The current protocol for treatment of HIV infections involves the simultaneous use of three drugs, which helps to minimize the acquisition of resistance.

There are three general strategies by which pathogens develop drug resistance. Pathogens can (1) produce an enzyme that destroys the drug, (2) alter the molecular target of the drug so that it is no longer sensitive to the drug, or (3) prevent access to the target by, for example, actively pumping the drug out of the pathogen. Once a pathogen has chanced upon an effective strategy, the newly acquired or mutated genes that confer that resistance are frequently spread throughout the pathogen population and may even be transferred to pathogens of different species that are treated with the same drug. The highly effective and very expensive antibiotic *vancomycin*, for example, has been used as a treatment of last resort for many severe hospital-acquired bacterial infections that are already resistant to most other known antibiotics.

Vancomycin prevents one step in bacterial cell wall biosynthesis, by binding to part of the growing peptidoglycan chain and preventing it from being cross-linked to other chains. Resistance can arise if the bacterium synthesizes a different type of cell wall, using different subunits that do not bind vancomycin. The most effective type of vancomycin resistance depends on a transposon that encodes seven genes. The products of these genes work together to sense the presence of vancomycin, shut down the normal pathway for bacterial cell wall synthesis, and generate a different type of cell wall. Although the joining of these genes into a single transposon must have been a

difficult evolutionary task (it took 15 years for vancomycin resistance to develop, rather than the typical lag of a year or two), the transposon can now be readily transmitted to many other pathogenic bacterial species.

Like most other aspects of infectious disease, the problem of drug resistance has been exacerbated by human behavior. Many patients take antibiotics for viral diseases that are not helped by the drugs, including influenza, colds, and earaches. Persistent and chronic misuse of antibiotics in this way can eventually result in the antibiotic resistance of the normal flora, which can then transfer the resistance to pathogens. Several antibiotic-resistant outbreaks of infectious diarrhea caused by *Shigella flexneri*, for example, originated in this way. The problem is particularly severe in countries where antibiotics are available without a physician's prescription, as in Brazil, where more than 80% of the strains of *S. flexneri* found in infected patients are resistant to four or more antibiotics.

Antibiotics are also misused in agriculture, where they are commonly employed as food additives to promote the growth of healthy animals. An antibiotic closely related to vancomycin was commonly added to cattle feed in Europe. Resistance arising in the normal flora of these animals is widely believed to be one of the original sources for the vancomycin resistance that is now seen in life-threatening human infections. [↑ TOP](#)

Summary

All pathogens share the ability to interact with host cells in ways that promote replication and spread of the pathogen, but these host-pathogen interactions are diverse. Pathogens often colonize the host by adhering to or invading through the epithelial surfaces that line the lungs, gut, bladder, and other surfaces in direct contact with the environment. Intracellular pathogens, including all viruses and many bacteria and protozoa, replicate inside a host cell, which they invade by one of a variety of mechanisms. Viruses rely largely on receptor-mediated endocytosis for host cell entry, while bacteria exploit cell adhesion and phagocytic pathways. Protozoa employ unique invasion strategies that usually require significant metabolic expense. Once inside, intracellular pathogens seek out a niche that is favorable for their replication, frequently altering host cell membrane traffic and exploiting the cytoskeleton for intracellular movement. Besides altering the behavior of individual host cells, pathogens frequently alter the behavior of the host organism in ways that favor spread to a new host. Pathogens evolve rapidly, so new infectious diseases frequently emerge, and old diseases acquire new ways to evade human attempts at treatment, prevention, and eradication. [↑ TOP](#)

Figure 25-18. The spread of plague. This micrograph shows the digestive tract dissected from a flea that had dined about two weeks previously on the blood of an animal infected with the plague bacterium, *Yersinia pestis*. The bacteria multiplied in the flea gut to produce large cohesive aggregates, indicated by the *red* arrows; the bacterial mass on the left is occluding the passage between the esophagus and the midgut. This type of blockage prevents a flea from digesting its blood meals, thereby causing it to bite repeatedly, disseminating the infection. (From B.J. Hinnebusch, E.R. Fischer and T.G. Schwann, *J. Infect. Dis.* 178:1406–1415, 1998. © The University of Chicago Press.)

Figure 25-20. Interaction of enteropathogenic *E. coli* (EPEC) with host cells. (A) When EPEC contacts an epithelial cell in the lining of the human gut, it delivers a bacterial protein, Tir, into the host cell through a type III secretion system. Tir then inserts into the plasma membrane of the host cell, where it functions as a receptor for the bacterial adhesin intimin. (B) The intracellular domain of Tir is phosphorylated on a tyrosine residue by a host cell protein tyrosine kinase. Phosphorylated Tir then probably recruits a Rho family GTPase, which triggers actin polymerization; it also recruits other host cell cytoskeletal factors that interact with actin. Consequently, a bundle of actin filaments is assembled underneath the bacterium to form an actin pedestal. (C) EPEC on a pedestal. In this fluorescence micrograph, the DNA of the EPEC and host cell are labeled in *blue*, Tir protein is labeled in *green*, and host cell actin filaments are labeled in *red*. Figure 25-21. Receptor and co-receptors for HIV. All strains of HIV require CD4 as a primary receptor. Early in an infection, most of the viruses use CCR5 as a co-receptor, allowing them to infect macrophages and their precursors, monocytes. As the infection progresses, mutant variants arise that now use CXCR4 as a co-receptor, enabling them to efficiently infect T cells. Invasion of either virus type can be blocked by the natural ligand for the chemokine receptors (Sdf-1 for CXCR4, and Rantes, Mip-1 α , or Mip-1 β for CCR5).

Figure 25-22. Four virus uncoating strategies. (A) Some enveloped viruses, such as HIV, fuse directly with the host cell plasma membrane to release their capsid (*green*) into the cytosol. (B) Other enveloped viruses, such as influenza virus, first bind to cell-surface receptors, triggering receptor-mediated endocytosis. When the endosome acidifies, the virus envelope fuses with the endosomal membrane, releasing the nucleocapsid (*blue*) into the cytosol. (C) Poliovirus, a nonenveloped virus, binds to a receptor (*green*) on the host cell surface and then forms a pore in the host cell membrane to extrude its RNA genome (*blue*). (D) Adenovirus, another nonenveloped virus, uses a more complicated strategy. It induces receptor-mediated endocytosis and then disrupts the endosomal membrane, releasing part of the capsid into the cytosol. The capsid eventually docks onto a nuclear pore and releases its DNA genome (*red*) directly into the nucleus.

Figure 25-23. The entry strategy used by the influenza virus. The globular heads of the viral hemagglutinin (HA) mediate binding of the virus to sialic-acid-containing cell-surface receptors. The virus-receptor complexes are endocytosed and, in the acidic environment of the endosome, the loop region of the HA becomes a coiled-coil, moving the fusion peptide to the top of the molecule, near the endosomal membrane. To allow release of the viral genome into the cytosol, H⁺ ions in the endosome enter the virus through an ion channel in the viral membrane, releasing the RNA genome (*blue*) from the capsid coat. The fusion of the viral and endocytic membranes allows the viral genome to enter the cytosol.

Figure 25-29. Selective destruction of the phagosomal membrane by *Listeria monocytogenes*. *L. monocytogenes* attaches to E-cadherin on the surface of epithelial cells and induces its own uptake by the zipper mechanism (see Figure 25-25A). Within the phagosome, the bacterium secretes the hydrophobic protein hemolysin, which forms oligomers in the host cell membrane, thereby creating large pores and eventually disrupting the membrane. Once in the host cell cytosol, the bacteria begin to replicate and continue to secrete hemolysin. Because the hemolysin is rapidly degraded by proteasomes, the host cell plasma membrane remains intact.

Figure 25-31. Complicated strategies for viral envelope acquisition. (A) Herpes virus capsids are assembled in the nucleus and then bud through the inner nuclear membrane, acquiring a membrane coat. They then apparently lose this coat when they fuse with the outer nuclear membrane to escape into the cytosol. Subsequently, they bud into the Golgi apparatus, and bud out again on the other side, acquiring two new membrane coats. The virus then buds from the cell with a single membrane when its outer membrane fuses with the plasma membrane. (B) Vaccinia virus, which is closely related to the virus that causes smallpox, is assembled in "replication factories" deep within the cytosol. The first structure assembled contains two membranes acquired from the Golgi apparatus by a poorly defined wrapping mechanism. A variable proportion of these viral particles are then engulfed by the membranes of a second intracellular membrane-enclosed compartment. These viral particles have a total of four layers of membrane envelope. After fusion at the plasma membrane, the virus escapes with three membrane layers.

Figure 25-34. Molecular mechanisms for actin nucleation by various pathogens. The bacteria *Listeria monocytogenes* and *Shigella flexneri* and the virus vaccinia all move intracellularly using actin polymerization. To induce actin nucleation, all of these pathogens recruit and activate the ARP complex (see [Figure 16-28](#)), although each pathogen uses a different recruitment strategy. *L. monocytogenes* expresses a surface protein, ActA, that directly binds to and activates the ARP complex. *S. flexneri* expresses a surface protein, IcsA (unrelated to ActA), that recruits the host cell signaling protein N-WASp. N-WASp in turn recruits the ARP complex, along with other host proteins, including WIP (WASp-interacting protein). Vaccinia virus expresses an envelope protein that is phosphorylated on tyrosine by a host cell protein tyrosine kinase. The phosphorylated protein then recruits Nck, which binds WIP. WIP binds N-WASp, which recruits and activates the ARP complex. The more complicated cascade used by vaccinia is thought to closely resemble how the ARP complex is activated by chemotactic factors in motile eucaryotic cells. Despite these distinct molecular strategies, the actin comet tails formed by all three pathogens look very similar, and the pathogens move at similar speeds inside infected cells.

Figure 25-37. Antigenic variation in trypanosomes. (A) There are about 1000 distinct VSG genes in *Trypanosoma brucei* but only one site for VSG gene expression. An inactive gene is copied into the expression site by gene conversion, where it is now expressed. Rare switching events allow the trypanosome to change repeatedly the surface antigen it expresses. (B) A person infected with trypanosomes expressing VSG^a quickly mounts a protective antibody response, which results in clearance of most of the parasites expressing this antigen. However, a few of the trypanosomes may have switched to expression of VSG^b, which can now proliferate until they are cleared by anti-VSG^b antibodies. By that time, however, some parasites will have switched to VSG^c, and so the cycle repeats seemingly indefinitely.

Figure 25-38. Diversification of HIV-1, HIV-2, and related strains of SIV.

The genetic distance between any two viral isolates is found by following the shortest path joining them in the tree. HIV-1 is divided into two groups, major (M) and outlier (O). The HIV-1 M group is responsible for the global AIDS epidemic. HIV-1 M is further subdivided into several subtypes, A through G. Subtype B is dominant in America and Europe, B, C, and E predominate in Asia, and all subtypes are found in Africa. At least two monkey viruses, chimpanzee and mandrill, are more closely related to HIV-1 than is HIV-2, suggesting that HIV-1 and HIV-2 arose independently of one another. HIV-1 and SIV-CPZ (chimpanzee) are estimated to have diverged about 1930. This tree was constructed from the nucleotide sequences of the *gag* gene, using a database containing about 16,000 sequences from virus samples isolated around the world.

Pathogens, Infection, and Innate Immunity

Innate Immunity

Humans are exposed to millions of potential pathogens daily, through contact, ingestion, and inhalation. Our ability to avoid infection depends in part on the adaptive immune system (discussed in [Chapter 24](#)), which remembers previous encounters with specific pathogens and destroys them when they attack again. Adaptive immune responses, however, are slow to develop on first exposure to a new pathogen, as specific clones of B and T cells have to become activated and expand; it can therefore take a week or so before the responses are effective. By contrast, a single bacterium with a doubling time of one hour can produce almost 20 million progeny, a full-blown infection, in a single day. Therefore, during the first critical hours and days of exposure to a new pathogen, we rely on our **innate immune system** to protect us from infection.

Innate immune responses are not specific to a particular pathogen in the way that the adaptive immune responses are. They depend on a group of proteins and phagocytic cells that recognize conserved features of pathogens and become quickly activated to help destroy invaders. Whereas the adaptive immune system arose in evolution less than 500 million years ago and is confined to vertebrates, innate immune responses have been found among both vertebrates and invertebrates, as well as in plants, and the basic mechanisms that regulate them are conserved. As discussed in [Chapter 24](#), the innate immune responses in vertebrates are also required to activate adaptive immune responses.

Epithelial Surfaces Help Prevent Infection

In vertebrates, the skin and other epithelial surfaces, including those lining the lung and gut ([Figure 25-39](#)), provide a physical barrier between the inside of the body and the outside world. Tight junctions (discussed in [Chapter 19](#)) between neighboring cells prevent easy entry by potential pathogens. The interior epithelial surfaces are also covered with a mucus layer that protects these surfaces against microbial, mechanical, and chemical insults; many amphibians and fish also have a mucus layer covering their skin. The slimy mucus coating is made primarily of secreted mucin and other glycoproteins, and it physically helps prevent pathogens from adhering to the epithelium. It

[Figure 25-49. A](#)

[natural killer \(NK\) cell...](#)

also facilitates their clearance by beating cilia on the epithelial cells (discussed in [Chapter 22](#)).

The mucus layer also contains substances that kill pathogens or inhibit their growth. Among the most abundant of these are antimicrobial peptides, called **defensins**, which are found in all animals and plants. They are generally short (12–50 amino acids), positively charged, and have hydrophobic or amphipathic domains in their folded structure. They constitute a diverse family with a broad spectrum of antimicrobial activity, including the ability to kill or inactivate Gram-negative and Gram-positive bacteria, fungi (including yeasts), parasites (including protozoa and nematodes), and even enveloped viruses like HIV. Defensins are also the most abundant protein type in neutrophils (see below), which use them to kill phagocytosed pathogens.

It is still uncertain how defensins kill pathogens. One possibility is that they use their hydrophobic or amphipathic domains to insert into the membrane of their victims, thereby disrupting membrane integrity. Some of their selectivity for pathogens over host cells may come from their preference for membranes that do not contain cholesterol. After disrupting the membrane of the pathogen, the positively-charged peptides may also interact with various negatively-charged targets within the microbe, including DNA. Because of the relatively nonspecific nature of the interaction between defensins and the microbes they kill, it is difficult for the microbes to acquire resistance to the defensins. Thus, in principle, defensins might be useful therapeutic agents to combat infection, either alone or in combination with more traditional drugs. [↑ TOP](#)

Human Cells Recognize Conserved Features of Pathogens

Microorganisms do occasionally breach the epithelial barricades. It is then up to the innate and adaptive immune systems to recognize and destroy them, without harming the host. Consequently, the immune systems must be able to distinguish self from nonself. We discuss in [Chapter 24](#) how the adaptive immune system does this. The innate immune system relies on the recognition of particular types of molecules that are common to many pathogens but are absent in the host. These pathogen-associated molecules (called *pathogen-associated immunostimulants*) stimulate two types of innate immune responses—*inflammatory responses* (discussed below) and phagocytosis by cells such as neutrophils and macrophages. Both of these responses can occur quickly, even if the host has never been previously exposed to a particular pathogen.

The **pathogen-associated immunostimulants** are of various types.

Prokaryotic translation initiation differs from eukaryotic translation initiation in that *formylated methionine*, rather than regular methionine, is generally used as the first amino acid. Therefore, any peptide containing formylmethionine at the N-terminus must be of bacterial origin. Formylmethionine-containing peptides act as very potent chemoattractants for neutrophils, which migrate

quickly to the source of such peptides and engulf the bacteria that are producing them (see [Figure 16-96](#)).

In addition, the outer surface of many microorganisms is composed of molecules that do not occur in their multicellular hosts, and these molecules also act as immunostimulants. They include the peptidoglycan cell wall and flagella of bacteria, as well as lipopolysaccharide (LPS) on Gram-negative bacteria ([Figure 25-40](#)) and teichoic acids on Gram-positive bacteria (see [Figure 25-4D](#)). They also include molecules in the cell walls of fungi such as zymosan, glucan, and chitin. Many parasites also contain unique membrane components that act as immunostimulants, including glycosylphosphatidylinositol in *Plasmodium*.

Short sequences in bacterial DNA can also act as immunostimulants. The culprit is a "CpG motif", which consists of the unmethylated dinucleotide CpG flanked by two 5' purine residues and two 3' pyrimidines. This short sequence is at least twenty times less common in vertebrate DNA than in bacterial DNA, and it can activate macrophages, stimulate an inflammatory response, and increase antibody production by B cells.

The various classes of pathogen-associated immunostimulants often occur on the pathogen surface in repeating patterns. They are recognized by several types of dedicated receptors in the host, that are collectively called *pattern recognition receptors*. These receptors include soluble receptors in the blood (components of the complement system) and membrane-bound receptors on the surface of host cells (members of the Toll-like receptor family). The cell-surface receptors have two functions: they initiate the phagocytosis of the pathogen, and they stimulate a program of gene expression in the host cell for stimulating innate immune responses. The soluble receptors also aid in the phagocytosis and, in some cases, the direct killing of the pathogen. [↑ TOP](#)

Complement Activation Targets Pathogens for Phagocytosis or Lysis

The complement system consists of about 20 interacting soluble proteins that are made mainly by the liver and circulate in the blood and extracellular fluid. Most are inactive until they are triggered by an infection. They were originally identified by their ability to amplify and "complement" the action of antibodies, but some components of complement are also pattern recognition receptors that can be activated directly by pathogen-associated immunostimulants.

The *early complement components* are activated first. There are three sets of these, belonging to three distinct pathways of complement activation—the *classical pathway*, the *lectin pathway*, and the *alternative pathway*. The early components of all three pathways act locally to activate C3, which is the

pivotal component of complement ([Figure 25-41](#)). Individuals with a deficiency in C3 are subject to repeated bacterial infections. The early components and C3 are all proenzymes, which are activated sequentially by proteolytic cleavage. The cleavage of each proenzyme in the series activates the next component to generate a serine protease, which cleaves the next proenzyme in the series, and so on. Since each activated enzyme cleaves many molecules of the next proenzyme in the chain, the activation of the early components consists of an amplifying, proteolytic cascade.

Many of these cleavages liberate a biologically active small peptide fragment and a membrane-binding larger fragment. The binding of the large fragment to a cell membrane, usually the surface of a pathogen, helps to carry out the next reaction in the sequence. In this way, complement activation is confined largely to the particular cell surface where it began. The larger fragment of C3, called C3b, binds covalently to the surface of the pathogen. Once in place, it not only acts as a protease to catalyze the subsequent steps in the complement cascade, but it also is recognized by specific receptors on phagocytic cells that enhance the ability of these cells to phagocytose the pathogen. The smaller fragment of C3 (called C3a), as well as fragments of C4 and C5 (see [Figure 25-41](#)), act independently as diffusible signals to promote an inflammatory response by recruiting phagocytes and lymphocytes to the site of infection.

The classical pathway is activated by IgG or IgM antibody molecules (discussed in [Chapter 24](#)) bound to the surface of a microbe. **Mannan-binding lectin**, the protein that initiates the second pathway of complement activation, is a serum protein that forms clusters of six carbohydrate-binding heads around a central collagen-like stalk. This assembly binds specifically to mannose and fucose residues in bacterial cell walls that have the correct spacing and orientation to match up perfectly with the six carbohydrate-binding sites, providing a good example of a pattern recognition receptor. These initial binding events in the classical and lectin pathways cause the recruitment and activation of the early complement components. In the **alternative pathway**, C3 is spontaneously activated at low levels, and the resulting C3b covalently attaches to both host cells and pathogens. Host cells produce a series of proteins that prevent the complement reaction from proceeding on their cell surfaces. Because pathogens lack these proteins, they are singled out for destruction. Activation of the classical or lectin pathways also activates the alternative pathway through a positive feedback loop, amplifying their effects.

Membrane-immobilized C3b, produced by any of the three pathways, triggers a further cascade of reactions that leads to the assembly of the late components to form *membrane attack complexes* ([Figure 25-42](#)). These complexes assemble in the pathogen membrane near the site of C3 activation and have a characteristic appearance in negatively stained electron micrographs, where they are seen to form aqueous pores through the membrane ([Figure 25-43](#)). For this reason, and because they perturb the structure of the bilayer in their vicinity, they make the membrane leaky and can, in some cases, cause the

microbial cell to lyse, much like the defensins mentioned earlier.

The self-amplifying, inflammatory, and destructive properties of the complement cascade make it essential that key activated components be rapidly inactivated after they are generated to ensure that the attack does not spread to nearby host cells. Deactivation is achieved in at least two ways. First, specific inhibitor proteins in the blood or on the surface of host cells terminate the cascade, by either binding or cleaving certain components once they have been activated by proteolytic cleavage. Second, many of the activated components in the cascade are unstable; unless they bind immediately to either an appropriate component in the cascade or to a nearby membrane, they rapidly become inactive. [↑ TOP](#)

Toll-like Proteins Are an Ancient Family of Pattern Recognition Receptors

Many of the mammalian cell-surface pattern recognition receptors responsible for triggering host cell gene expression in response to pathogens are members of the **Toll-like receptor (TLR)** family. *Drosophila* Toll is a transmembrane protein with a large extracellular domain consisting of a series of leucine-rich repeats (see [Figure 15-76](#)). It was originally identified as a protein involved in the establishment of dorso-ventral polarity in developing fly embryos (discussed in [Chapter 21](#)). It is also involved, however, in the adult fly's resistance to fungal infections. The intracellular signal transduction pathway activated downstream of Toll when a fly is exposed to a pathogenic fungus leads to the translocation of the NF- κ B protein (discussed in [Chapter 15](#)) into the nucleus, where it activates the transcription of various genes, including those encoding antifungal defensins. Another member of the Toll family in *Drosophila* is activated by exposure to pathogenic bacteria, leading to the production of an antibacterial defensin.

Humans have at least ten TLRs, several of which have been shown to play important parts in innate immune recognition of pathogen-associated immunostimulants, including lipopolysaccharide, peptidoglycan, zymosan, bacterial flagella, and CpG DNA. As with *Drosophila* Toll family members, the different human TLRs are activated in response to different ligands, although many of them use the NF- κ B signaling pathway ([Figure 25-44](#)). In mammals, TLR activation stimulates the expression of molecules that both initiate an inflammatory response (discussed below) and help induce adaptive immune responses. TLRs are abundant on the surface of macrophages and neutrophils, as well as on the epithelial cells lining the lung and gut. They act as an alarm system to alert both the innate and adaptive immune systems that an infection is brewing.

Molecules related to Toll and TLRs are apparently involved in innate immunity in all multicellular organisms. In plants, proteins with leucine-rich repeats and with domains homologous to the cytosolic portion of the TLRs are

required for resistance to fungal, bacterial, and viral pathogens (Figure 25-45). Thus, at least two parts of the innate immune system—the defensins and the TLRs—seem to be evolutionarily very ancient, perhaps predating the split between animals and plants over a billion years ago. Their conservation during evolution indicates the importance of these innate responses in the defense against microbial pathogens. [↑ TOP](#)

Phagocytic Cells Seek, Engulf, and Destroy Pathogens

In all animals, invertebrate as well as vertebrate, the recognition of a microbial invader is usually quickly followed by its engulfment by a phagocytic cell. Plants, however, lack this type of innate immune response. In vertebrates, *macrophages* reside in tissues throughout the body and are especially abundant in areas where infections are likely to arise, including the lungs and gut. They are also present in large numbers in connective tissues, the liver, and the spleen. These long-lived cells patrol the tissues of the body and are among the first cells to encounter invading microbes. The second major family of phagocytic cells in vertebrates, the *neutrophils*, are short-lived cells, which are abundant in blood but are not present in normal, healthy tissues. They are rapidly recruited to sites of infection both by activated macrophages and by molecules such as formylmethionine-containing peptides released by the microbes themselves.

Macrophages and neutrophils display a variety of cell-surface receptors that enable them to recognize and engulf pathogens. These include pattern recognition receptors such as TLRs. In addition, they have cell-surface receptors for the Fc portion of antibodies produced by the adaptive immune system, as well as for the C3b component of complement. Ligand binding to any of these receptors induces actin polymerization at the site of pathogen attachment, causing the phagocyte's plasma membrane to surround the pathogen and engulf it in a large membrane-enclosed phagosome (Figure 25-46).

Once the pathogen has been phagocytosed, the macrophage or neutrophil unleashes an impressive armory of weapons to kill it. The phagosome is acidified and fuses with lysosomes, which contain lysozyme and acid hydrolases that can degrade bacterial cell walls and proteins. The lysosomes also contain defensins, which make up about 15% of the total protein in neutrophils. In addition, the phagocytes assemble a *NADPH oxidase complex* on the phagosomal membrane that catalyzes the production of a series of highly toxic oxygen-derived compounds, including superoxide (O_2^-),

hypochlorite (HOCl, the active ingredient in bleach), hydrogen peroxide, hydroxyl radicals, and nitric oxide (NO). The production of these toxic compounds is accompanied by a transient increase in oxygen consumption by the cells, called the *respiratory burst*. Whereas macrophages will generally survive this killing frenzy and continue to patrol tissues for other pathogens, neutrophils usually die. Dead and dying neutrophils are a major component of

the pus that forms in acutely infected wounds. The distinctive greenish tint of pus is due to the abundance in neutrophils of the copper-containing enzyme myeloperoxidase, which is one of the components active in the respiratory burst.

If a pathogen is too large to be successfully phagocytosed (if it is a large parasite such as a nematode, for example), a group of macrophages, neutrophils, or eosinophils (discussed in [Chapter 22](#)) will gather around the invader. They will secrete their defensins and other lysosomal products by exocytosis and will also release the toxic products of the respiratory burst ([Figure 25-47](#)). This barrage is generally sufficient to destroy the pathogen.

Many pathogens have developed strategies that allow them to avoid being ingested by phagocytes. Some Gram-positive bacteria coat themselves with a very thick, slimy polysaccharide coat, or *capsule*, that is not recognized by complement or any phagocyte receptor. Other pathogens are phagocytosed but avoid being killed; as we saw earlier, *Mycobacterium tuberculosis* prevents the maturation of the phagosome and thereby survives. Some pathogens escape the phagosome entirely, and yet others secrete enzymes that detoxify the products of the respiratory burst. For such wily pathogens, these first lines of defense are insufficient to clear the infection, and adaptive immune responses are required to contain them. [↑ TOP](#)

Activated Macrophages Recruit Additional Phagocytic Cells to Sites of Infection

When a pathogen invades a tissue, it almost always elicits an inflammatory response. This response is characterized by pain, redness, heat, and swelling at the site of infection, all caused by changes in local blood vessels. The blood vessels dilate and become permeable to fluid and proteins, leading to local swelling and an accumulation of blood proteins that aid in defense, including the components of the complement cascade. At the same time, the endothelial cells lining the local blood vessels are stimulated to express cell adhesion proteins (discussed in [Chapter 19](#)) that facilitate the attachment and extravasation of white blood cells, including neutrophils, lymphocytes, and monocytes (the precursors of macrophages).

The inflammatory response is mediated by a variety of signaling molecules. Activation of TLRs results in the production of both lipid signaling molecules such as prostaglandins and protein (or peptide) signaling molecules such as cytokines (discussed in [Chapter 15](#)), all of which contribute to the inflammatory response. The proteolytic release of complement fragments also contribute. Some of the cytokines produced by activated macrophages are chemoattractants (known as *chemokines*). Some of these attract neutrophils, which are the first cells recruited in large numbers to the site of the new infection. Others later attract monocytes and dendritic cells. The dendritic cells pick up antigens from the invading pathogens and carry them to nearby lymph

nodes, where they present the antigens to lymphocytes to marshal the forces of the adaptive immune system (discussed in [Chapter 24](#)). Other cytokines trigger *fever*, a rise in body temperature. On balance, fever helps the immune system in the fight against infection, since most bacterial and viral pathogens grow better at lower temperatures, whereas adaptive immune responses are more potent at higher temperatures.

Some proinflammatory signaling molecules stimulate endothelial cells to express proteins that trigger blood clotting in local small vessels. By occluding the vessels and cutting off blood flow, this response can help prevent the pathogen from entering the bloodstream and spreading the infection to other parts of the body.

The same inflammatory responses, however, which are so effective at controlling local infections, can have disastrous consequences when they occur in a disseminated infection in the bloodstream, a condition called *sepsis*. The systemic release of proinflammatory signaling molecules into the blood causes dilation of blood vessels, loss of plasma volume, and widespread blood clotting, which is an often fatal condition known as *septic shock*. Inappropriate or overzealous inflammatory responses are also associated with some chronic conditions, such as *asthma* ([Figure 25-48](#)).

Just as with phagocytosis, some pathogens have developed mechanisms to either prevent the inflammatory response or, in some cases, take advantage of it to spread the infection. Many viruses, for example, encode potent cytokine antagonists that block aspects of the inflammatory response. Some of these are simply modified forms of cytokine receptors, encoded by genes acquired by the viral genome from the host. They bind the cytokines with high affinity and block their activity. Some bacteria, such as *Salmonella*, induce an inflammatory response in the gut at the initial site of infection, thereby recruiting macrophages and neutrophils that they then invade. In this way, the bacteria hitch a ride to other tissues in the body. [↑ TOP](#)

Virus-Infected Cells Take Drastic Measures to Prevent Viral Replication

The pathogen-associated immunostimulants on the surface of bacteria and parasites that are so important in eliciting innate immune responses are generally not present on the surface of viruses. Viral proteins are constructed by the host cell ribosomes, and the membranes of enveloped viruses are composed of host cell lipids. The only unusual molecule associated with viruses is the double-stranded RNA (dsRNA) that is an intermediate in the life cycle of many viruses. Host cells can detect the presence of dsRNA and initiate a program of drastic responses in attempt to eliminate it.

The program occurs in two steps. First, the cells degrade the dsRNA into small fragments (about 21–25 nucleotide pairs in length). These fragments bind to

any single-stranded RNA (ssRNA) in the host cell with the same sequence as either strand of the dsRNA fragment, leading to the destruction of the ssRNA. This dsRNA-directed ssRNA destruction is the basis of the technique of *RNA interference* (RNAi) that is used by researchers to block specific gene expression (discussed in [Chapter 8](#)). Second, the dsRNA induces the host cell to produce and secrete two cytokines—*interferon α* (*IFN- α*) and *interferon β* (*IFN- β*), which act in both an autocrine fashion on the infected cell and a paracrine fashion on uninfected neighbors. The binding of the interferons to their cell-surface receptors stimulates specific gene transcription by the Jak/STAT intracellular signaling pathway (see [Figure 15-63](#)), leading to the activation of a latent ribonuclease, which nonspecifically degrades ssRNA. It also leads to the activation of a protein kinase that phosphorylates and inactivates the protein synthesis initiation factor eIF-2, shutting down most protein synthesis in the embattled host cell. Apparently, by destroying most of the RNA it contains and transiently halting most protein synthesis, the cell inhibits viral replication without killing itself. In some cases, however, a cell infected with a virus is persuaded by white blood cells to destroy itself to prevent the virus from replicating.  [TOP](#)

Natural Killer Cells Induce Virus-Infected Cells to Kill Themselves

Another way that the interferons help vertebrates defend themselves against viruses is by stimulating both innate and adaptive cellular immune responses. In [Chapter 24](#), we discuss how interferons enhance the expression of class I MHC proteins, which present viral antigens to cytotoxic T lymphocytes (see [Figure 24-48](#)). Here, we consider how interferons enhance the activity of natural killer cells (NK cells), which are part of the innate immune system. Like cytotoxic T cells, NK cells destroy virus-infected cells by inducing the infected cell to kill itself by undergoing apoptosis. Unlike T cells, however, NK cells do not express antigen-specific receptors. How, then, do they distinguish virus-infected cells from uninfected cells?

NK cells monitor the level of class I MHC proteins, which are expressed on the surface of most vertebrate cells. The presence of high levels of these proteins inhibits the killing activity of NK cells, so that the NK cells selectively kill cells expressing low levels, including both virally-infected cells and some cancer cells ([Figure 25-49](#)). Many viruses have developed mechanisms to inhibit the expression of class I MHC molecules on the surface of the cells they infect, in order to avoid detection by cytotoxic T lymphocytes. Adenovirus and HIV, for example, encode proteins that block class I MHC gene transcription. Herpes simplex virus and cytomegalovirus block the peptide translocators in the ER membrane that transport proteasome-derived peptides from the cytosol into the lumen of the ER; such peptides are required for newly-made class I MHC proteins to assemble in the ER membrane and be transported through the Golgi apparatus to the cell surface (see [Figure 24-58](#)). Cytomegalovirus causes the retrotranslocation of class I MHC proteins from

the ER membrane into the cytosol, where they are rapidly degraded by proteasomes. Proteins encoded by still other viruses prevent the delivery of assembled class I MHC proteins from the ER to the Golgi apparatus, or from the Golgi apparatus to the plasma membrane. By evading recognition by cytotoxic T cells in these ways, however, a virus incurs the wrath of NK cells. The local production of IFN- α and IFN- β activates the killing activity of NK cells and also increases the expression of class I MHC proteins in uninfected cells. The cells infected with a virus that blocks class I MHC expression are thereby exposed and become the victims of the activated NK cells. Thus, it is difficult or impossible for viruses to hide from both the innate and adaptive immune systems simultaneously.

Both NK cells and cytotoxic T lymphocytes kill infected target cells by inducing them to undergo apoptosis before the virus has had a chance to replicate. It is not surprising, then, that many viruses have acquired mechanisms to inhibit apoptosis, particularly early in infection. As discussed in [Chapter 17](#), apoptosis depends on an intracellular proteolytic cascade, which the cytotoxic cell can trigger either through the activation of cell-surface death receptors or by injecting a proteolytic enzyme into the target cell (see [Figure 24-46](#)). Viral proteins can interfere with nearly every step in these pathways. In some cases, however, viruses encode proteins that act late in their replication cycle to induce apoptosis in the host cell, thereby releasing progeny virus that can infect neighboring cells.

The battle between pathogens and host defenses is remarkably balanced. At present, humans seem to be gaining a slight advantage, using public sanitation measures, vaccines, and drugs to aid the efforts of our innate and adaptive immune systems. However, infectious and parasitic diseases are still the leading cause of death worldwide, and new epidemics such as AIDS continue to emerge. The rapid evolution of pathogens and the almost infinite variety of ways that they can invade the human body and elude immune responses will prevent us from ever winning the battle completely. [↑ TOP](#)

Summary

The innate immune responses are the first line of defense against invading pathogens. They are also required to initiate specific adaptive immune responses. Innate immune responses rely on the body's ability to recognize conserved features of pathogens that are not present in the uninfected host. These include many types of molecules on microbial surfaces and the double-stranded RNA of some viruses. Many of these pathogen-specific molecules are recognized by Toll-like receptor proteins, which are found in plants and in invertebrate and vertebrate animals. In vertebrates, microbial surface molecules also activate complement, a group of blood proteins that act together to disrupt the membrane of the microorganism, to target microorganisms for phagocytosis by macrophages and neutrophils, and to produce an inflammatory response. The phagocytic cells use a combination of

degradative enzymes, antimicrobial peptides, and reactive oxygen species to kill the invading microorganisms. In addition, they release signaling molecules that trigger an inflammatory response and begin to marshal the forces of the adaptive immune system. Cells infected with viruses produce interferons, which induce a series of cell responses to inhibit viral replication and activate the killing activities of natural killer cells and cytotoxic T lymphocytes. hydrophobic membrane anchor is made up of two linked glucosamine sugars attached to three phosphates and six fatty acid tails. This basic structure is elaborated by attachment of a long, usually highly branched, chain of sugars. This drawing shows the simplest type of LPS that will allow *E. coli* to live; it has just two sugar molecules in the chain, both 3-deoxy-D-manno-octulosonic acid. At the position marked by the *arrow*, wild-type Gram-negative bacteria also attach a *core saccharide* made up of eight to twelve linked sugars and a long *O antigen*, which is made up of an oligosaccharide unit that is repeated many (up to 40) times. The sugars making up the core saccharide and O antigen vary from one bacterial species to another and even among different strains of the same species. All forms of LPS are highly immunogenic.

Figure 25-41. The principal stages in complement activation by the classical, lectin, and alternative pathways. In all three pathways, the reactions of complement activation usually take place on the surface of an invading microbe, such as a bacterium. C1–C9 and factors B and D are the reacting components of the complement system; various other components regulate the system. The early components are shown within *gray arrows*, while the late components are shown within a *brown arrow*.

Figure 25-42. Assembly of the late complement components to form a membrane attack complex. When C3b is produced by any of the three activation pathways, it is immobilized on a membrane, where it causes the cleavage of the first of the late components, C5, to produce C5a (not shown) and C5b. C5b remains loosely bound to C3b (not shown) and rapidly assembles with C6 and C7 to form C567, which then binds firmly via C7 to the membrane, as illustrated. To this complex is added one molecule of C8 to form C5678. The binding of a molecule of C9 to C5678 induces a conformational change in C9 that exposes a hydrophobic region and causes C9 to insert into the lipid bilayer of the target cell. This starts a chain reaction in which the altered C9 binds a second molecule of C9, where it can bind another molecule of C9, and so on. In this way, a large transmembrane channel is formed by a chain of C9 molecules.

Figure 25-44. The activation of a macrophage by lipopolysaccharide (LPS). LPS is bound by LPS-binding protein (LBP) in the blood, and the complex binds to the GPI-anchored receptor CD14 on the macrophage surface. The ternary complex then activates Toll-like receptor 4 (TLR4). Activated TLR4 recruits the adaptor protein MyD88, which interacts with the serine-threonine protein kinase IRAK. Recruitment of IRAK to the activated receptor complex results in its autophosphorylation and association with another adaptor protein, TRAF6. TRAF6, in turn, associates with and

activates a MAP kinase kinase kinase, TAK1. Via several intermediate steps, TAK1 activation leads to the phosphorylation and activation of the I κ B kinase (IKK). IKK phosphorylates the NF- κ B inhibitor, I κ B, inducing its degradation and releasing NF- κ B. By way of additional MAP kinases (ERK and JNK), TAK1 also activates the AP-1 transcription family members Jun and Fos, which, together with NF- κ B, activate the transcription of genes that promote immune and inflammatory responses (see also Figure 15-74).

Molecular Biology of the Cell

Glossary

α helix *see* **alpha helix**

ABC transporter proteins Large superfamily of membrane transport proteins that use the energy of hydrolysis of ATP to transfer peptides and a variety of small molecules across membranes.

acetyl Chemical group derived from acetic acid. Acetyl groups are important in metabolism and are added covalently to some proteins as a posttranslational modification.

acetyl CoA Small water-soluble molecule that carries acetyl groups in cells. It consists of an acetyl group linked to coenzyme A (CoA) by an easily hydrolyzable thioester bond. (See [Figure 2–62](#).)

acetylcholine receptor Ion channel that opens in response to binding of acetylcholine, thereby converting a chemical signal into an electrical one. Best understood example of a transmitter-gated channel. Sometimes called the nicotinic acetylcholine receptor to distinguish it from a muscarinic acetylcholine receptor, which is a G-protein-linked cell-surface receptor.

acetylcholine Neurotransmitter that functions at a class of chemical synapses known as cholinergic synapses. Found both in the brain and in the peripheral nervous system. It is the neurotransmitter at vertebrate neuromuscular junctions. (See [Figure 15–9](#).)

acid Substance that releases protons when dissolved in water, forming a hydronium ion (H_3O^+).

acid hydrolase Any of a group of diverse hydrolytic enzymes (including proteases, nucleases, glycosidases, etc.) that have their optimal activity at acid pH (around 5.0) and are found in lysosomes.

acquired immunological tolerance Unresponsiveness of the immune system to a given foreign antigen that can develop in some circumstances.

acrosomal vesicle Region at the head end of a sperm cell that contains a sac of hydrolytic enzymes used to digest the protective coating of the egg.

acrosome reaction Reaction that occurs when a sperm starts to enter an egg, in which the contents of the acrosomal vesicle are released, helping the sperm to penetrate the zona pellucida.

actin Abundant protein that forms actin filaments in all eucaryotic cells. The monomeric form is sometimes called globular or G-actin; the polymeric form is filamentous or F-actin.

actin-binding protein Protein that associates with either actin monomers or actin filaments in cells and modifies their properties. Examples include myosin, α -actinin, and profilin.

actin filament (microfilament) Helical protein filament formed by the polymerization of globular actin molecules. A major constituent of the cytoskeleton of all eucaryotic cells and part of the contractile apparatus of skeletal muscle. (See Panel 16–1, p. 909.)

action potential Rapid, transient, self-propagating electrical excitation in the plasma membrane of a cell such as a neuron or muscle cell. Action potentials, or nerve impulses, make possible long-distance signaling in the nervous system.

activated carrier Small diffusible molecule in cells that stores easily-exchangeable energy in the form of one or more energy-rich covalent bonds. Examples are ATP and NADPH. Also called a coenzyme.

activation energy Extra energy that must be possessed by atoms or molecules in addition to their ground-state energy in order to undergo a particular chemical reaction. (See [Figure 9–1](#).)

active site Region of an enzyme surface to which a substrate molecule binds in order to undergo a catalyzed reaction.

active transport Movement of a molecule across a membrane or other barrier driven by energy other than that stored in the electrochemical gradient of the transported molecule.

acyl group Functional group derived from a carboxylic acid ($\text{R}-\text{C}(=\text{O})\text{OH}$). (R represents an alkyl group, such as methyl.)

adaptation Adjustment of sensitivity following repeated stimulation. This is the mechanism that allows a neuron, a photodetector, or a bacterium to react to small changes in stimuli even against a high background level of stimulation.

adaptin Protein that binds clathrin to the membrane surface in clathrin-coated vesicles.

adaptive immune response Response of the vertebrate immune system to a specific antigen that typically generates immunological memory.

adaptor protein General term for proteins in intracellular signaling pathways that link different proteins in the pathway directly together.

adenomatous polyposis coli (APC) Tumor suppressor protein that forms part of a protein complex that recruits free cytoplasmic β -catenin and degrades it.

adenosine triphosphate *see* **ATP**

adenylyl cyclase (adenylate cyclase) Membrane-bound enzyme that catalyzes the formation of cyclic AMP from ATP. An important component of some intracellular signaling pathways.

adherens junction Cell junction in which the cytoplasmic face of the plasma membrane is attached to actin filaments. Examples include the adhesion belts linking adjacent epithelial cells and the focal contacts on the lower surface of cultured fibroblasts.

adhesion belt Beltlike adherens junction that encircles the apical end of an epithelial cell and attaches it to the adjoining cell. Also known as the **zonula adherens**.

adhesion plaque *see* **focal adhesion**.

adipocyte A fat cell.

ADP (adenosine 5'-diphosphate) Nucleotide that is produced by hydrolysis of the terminal phosphate of ATP. It regenerates ATP when phosphorylated by an energy-generating process such as oxidative phosphorylation. (*See* [Figure 2-57](#).)

adrenaline (epinephrine) Hormone released by chromaffin cells (in the adrenal gland) and by some neurons in response to stress. Produces "fight or flight" responses, including increased heart rate and blood sugar levels.

aerobic Describes a process that requires, or occurs in the presence of, gaseous oxygen (O_2).

affinity chromatography Type of chromatography in which the protein mixture to be purified is passed over a matrix to which specific ligands for the required protein are attached, so that the protein is retained on the matrix.

affinity constant (association constant) (K_a) Measure of the strength of binding of the components in a complex. For components A and B and a binding equilibrium $A + B \rightleftharpoons AB$, the association constant is given by $[AB]/[A][B]$, and is larger the tighter the binding between A and B. (*See also* **dissociation constant**.)

affinity maturation Progressive increase in the affinity of antibodies for the

immunizing antigen with the passage of time after immunization.

Akt *see* **protein kinase B**

alcohol Polar organic molecule that contains a functional hydroxyl group ($-\text{OH}$) bound to a carbon atom that is not in an aromatic ring. An example is ethyl alcohol ($\text{CH}_3\text{CH}_2\text{OH}$).

aldehyde Organic compound that contains the group. An example is glyceraldehyde. Can be oxidized to an acid or reduced to an alcohol.

alga (algae) Informal term used to describe a wide range of simple unicellular and multicellular eucaryotic photosynthetic organisms. Examples include *Nitella*, *Volvox*, and *Fucus*.

alkaloid Small but chemically complex nitrogen-containing metabolite produced by plants as a defense against herbivores. Examples include caffeine, morphine, and colchicine.

alkane (adjective aliphatic) Compound of carbon and hydrogen that has only single covalent bonds. An example is ethane (CH_3CH_3).

alkene Hydrocarbon with one or more carbon-carbon double bonds. An example is ethylene (CH_2CH_2).

alkyl group General term for a group of covalently linked carbon and hydrogen atoms such as methyl ($-\text{CH}_3$) or ethyl ($-\text{CH}_2\text{CH}_3$) groups. These groups can be formed by removing a hydrogen atom from an alkane.

allele One of a set of alternative forms of a gene. In a diploid cell each gene will have two alleles, each occupying the same position (locus) on homologous chromosomes.

allelic exclusion The expression of an immunoglobulin chain (or T cell receptor chain) gene from only one of the two homologous loci present for that gene in the lymphocyte.

allosteric protein Protein that changes from one conformation to another when it binds another molecule or when it is covalently modified. The change in conformation alters the activity of the protein and can form the basis of directed movement.

alpha helix (α helix) Common folding pattern in proteins in which a linear sequence of amino acids folds into a right-handed helix stabilized by internal hydrogen bonding between backbone atoms.

alternative RNA splicing The production of different proteins from the same RNA transcript by splicing it in different ways.

amide Molecule containing a carbonyl group linked to an amine.

amine Chemical group containing nitrogen and hydrogen. It becomes positively charged in water.

amino acid Organic molecule containing both an amino group and a carboxyl group. Those that serve as the building blocks of proteins are alpha amino acids, having both the amino and carboxyl groups linked to the same carbon atom. (See Panel 3–1, pp. 132–133.)

aminoacyl-tRNA synthetase Enzyme that attaches the correct amino acid to a tRNA molecule to form an aminoacyl-tRNA. (See [Figure 6–57](#).)

amino group Weakly basic functional group derived from ammonia (NH₃) in which one or more hydrogen atoms are replaced by another atom. In aqueous solution it can accept a proton and carry a positive charge.

amino terminus (N terminus) The end of a polypeptide chain that carries a free α -amino group.

aminoacyl tRNA Activated form of amino acid used in protein synthesis. Consists of an amino acid linked through a labile ester bond from its carboxyl group to a hydroxyl group on tRNA. (See [Figure 6–57](#).)

AMP (adenosine 5'-monophosphate) One of the four nucleotides in an RNA molecule. Two phosphates are added to AMP to form ATP. (See Panel 2–6, pp. 120–121.)

amphipathic Having both hydrophobic and hydrophilic regions, as in a phospholipid or a detergent molecule.

anabolism System of biosynthetic reactions in a cell by which large molecules are made from smaller ones.

anaerobic Describes a cell, organism, or metabolic process that functions in the absence of air or, more precisely, in the absence of molecular oxygen (O₂).

anaphase Stage of mitosis during which the two sets of chromosomes separate and move away from each other. Composed of **anaphase A** (chromosomes move toward the two spindle poles) and **anaphase B** (spindle poles move apart).

anaphase-promoting complex (APC) Ubiquitin ligase that promotes the destruction of a set of proteins, some of which initiate the separation of sister chromatids during the metaphase-to-anaphase transition during mitosis.

anchorage dependence Dependence of cell growth on attachment to a substratum.

anchoring junction Type of cell junction that attaches cells to neighboring

cells or to the extracellular matrix.

angiogenesis Growth of new blood vessels by sprouting from existing ones.

Ångstrom (Å) Unit of length used to measure atoms and molecules. Equal to 10^{-10} meter or 0.1 nanometer (nm).

animal pole In yolky eggs, that end free of yolk that cleaves more rapidly than the vegetal pole.

ankyrin Protein mainly responsible for attaching the spectrin cytoskeleton to the red blood cell plasma membrane.

antenna complex Part of a photosystem that captures light energy and channels it into the photochemical reaction center. It consists of protein complexes that bind large numbers of chlorophyll molecules and other pigments.

anterior Situated toward the head end of the body.

anteroposterior Describes the axis running from the head to the tail of the animal body.

antibiotic Substance such as penicillin or streptomycin that is toxic to microorganisms. Usually a product of a particular microorganism or plant.

antibody (immunoglobulin) Protein produced by B cells in response to a foreign molecule or invading microorganism. Often binds to the foreign molecule or cell extremely tightly, thereby inactivating it or marking it for destruction by phagocytosis or complement-induced lysis.

anticodon Sequence of three nucleotides in a transfer RNA molecule that is complementary to a three-nucleotide codon in a messenger RNA molecule.

antigen Molecule that is able to provoke an immune response.

antigenic determinant (epitope) Specific region of an antigenic molecule that binds to an antibody or a T cell receptor.

antigenic variation The ability to change the antigens displayed on the cell surface; a property of some pathogenic microorganisms that enables them to evade attack by the immune system.

antigen-presenting cell Cell that displays foreign antigen complexed with MHC molecules on its surface.

antiparallel Describes the relative orientation of the two strands in a DNA double helix; the polarity of one strand is oriented in the opposite direction to that of the other.

antiporter Carrier protein that transports two different ions or small molecules

across a membrane in opposite directions, either simultaneously or in sequence.

antisense RNA RNA complementary to a specific RNA transcript of a gene that can hybridize to the specific RNA and block its function.

APC *see* **adenomatous polyposis coli; anaphase-promoting complex**

apical Describes the tip of a cell, a structure, or an organ. The apical surface of an epithelial cell is the exposed free surface, opposite to the basal surface. The basal surface rests on the basal lamina that separates the epithelium from other tissue.

apoptosis Form of cell death, also known as programmed cell death, in which a 'suicide' program is activated within the cell, leading to fragmentation of the DNA, shrinkage of the cytoplasm, membrane changes and cell death without lysis or damage to neighboring cells. It is a normal phenomenon, occurring frequently in a multicellular organism.

aqueous Pertaining to water, as for example, in an aqueous solution.

archaea (singular archeon) Members of one of the two major divisions of procaryotes (the Archea), the other being the Bacteria.

ARF protein Monomeric GTPase responsible for regulating both COPI coat assembly and clathrin coat assembly at Golgi membranes.

aromatic Describes a molecule that contains carbon atoms in a ring, commonly drawn as linked through alternating single and double bonds. Often a molecule related to benzene.

ARP complex (ARP2/3 complex) Complex of proteins that nucleates actin filament growth from the minus end.

asexual reproduction Any type of reproduction (such as budding in *Hydra*, binary fission in bacteria, or mitotic division in eucaryotic microorganisms) that does not involve gamete formation and fusion. It produces an individual genetically identical to the parent.

association constant *see* **affinity constant**

aster Star-shaped system of microtubules emanating from a centrosome or from a pole of a mitotic spindle.

astral microtubule In the mitotic spindle, any of the microtubules radiating from the aster which are not attached to a kinetochore of a chromosome.

asymmetric cell division Cell division that produces two daughter cells that differ, for example in size or in the presence or absence of some cytoplasmic constituent.

atomic weight Mass of an atom relative to the mass of a hydrogen atom.

Essentially equal to the number of protons plus neutrons.

ATP (adenosine 5'-triphosphate) Nucleoside triphosphate composed of adenine, ribose, and three phosphate groups that is the principal carrier of chemical energy in cells. The terminal phosphate groups are highly reactive in the sense that their hydrolysis, or transfer to another molecule, takes place with release of a large amount of free energy. (See [Figure 2–26](#).)

ATP synthase Enzyme complex in the inner membrane of a mitochondrion and the thylakoid membrane of a chloroplast that catalyzes the formation of ATP from ADP and inorganic phosphate during oxidative phosphorylation and photosynthesis, respectively. Also present in the plasma membrane of bacteria.

ATPase Enzyme that catalyzes a process involving the hydrolysis of ATP. A large number of different proteins have ATPase activity.

autoantibody Antibody produced by an individual against a protein, or other potential antigen, of its own cells and tissues. Autoantibodies can cause autoimmune disease.

autocatalysis Reaction that is catalyzed by one of its products, creating a positive feedback (self-amplifying) effect on the reaction rate.

autocrine signaling Type of cell signaling in which a cell secretes signal molecules that act on itself or on other adjacent cells of the same type.

autoimmune disease A pathological state in which the body mounts an immune response against one or more of its own potential antigens.

autophagy Digestion of worn-out organelles by the cell's own lysosomes.

autoradiography Technique in which a radioactive object produces an image of itself on a photographic film. The image is called an autoradiograph or autoradiogram.

autosome Any chromosome other than a sex chromosome.

avidity Total binding strength of a polyvalent antibody with a polyvalent antigen.

Avogadro's number 6×10^{23} . This is the number of atoms in 1 gram of hydrogen, and thus in the atomic or molecular weight equivalent in grams of any element or molecule.

axon Long nerve cell process that is capable of rapidly conducting nerve impulses over long distances so as to deliver signals to other cells.

axonal transport Directed transport of organelles and molecules along a nerve cell axon. It can be anterograde (outward from the cell body) or retrograde (back toward the cell body).

axoneme Bundle of microtubules and associated proteins that forms the core of a cilium or flagellum in a eucaryotic cell and is responsible for their movements.

β sheet *see* **beta sheet**

B cell (B lymphocyte) Type of lymphocyte that makes antibodies.

bacteria (singular bacterium) Members of the Bacteria, one of the two major divisions of procaryotes, the other being the Archea. Most exist as single cells and some cause disease.

bacterial artificial chromosome (BAC) Cloning vector that can accommodate large pieces of DNA up to 1 million base pairs.

bacteriophage (phage) Any virus that infects bacteria. Bacteriophages were the first entities used for the study of molecular genetics and are now widely used as cloning vectors.

bacteriorhodopsin Pigmented protein found in the plasma membrane of a salt-loving bacterium, *Halobacterium halobium*. It pumps protons out of the cell in response to light.

basal Situated near the base. The basal surface of a cell is opposite the apical surface.

basal body Short cylindrical array of microtubules plus their associated proteins found at the base of a eucaryotic cell cilium or flagellum. Serves as a nucleation site for the growth of the axoneme. Closely similar in structure to a centriole.

basal lamina (basal laminae) Thin mat of extracellular matrix that separates epithelial sheets, and many other types of cells such as muscle or fat cells, from connective tissue.

base A substance that can accept a proton in solution. The purines and pyrimidines in DNA and RNA are organic nitrogenous bases and are often referred to simply as bases.

base pair Two nucleotides in an RNA or DNA molecule that are held together by hydrogen bonds — for example, G pairs with C, and A with T or U.

basic Having the properties of a base.

benign Describes tumors that are self-limiting in their growth and noninvasive.

benzene Molecule composed of a six-membered ring of carbon atoms, commonly drawn containing three alternating double bonds. The benzene ring occurs as part of many biological molecules.

beta-catenin (β -catenin) Multifunctional cytoplasmic protein that is involved

in cadherin-mediated cell–cell adhesion, linking cadherins to the actin cytoskeleton. Can also act independently as a gene regulatory protein. Has an important role in animal development as part of a Wnt signaling pathway.

beta sheet (β sheet) Common structural motif in proteins in which different sections of the polypeptide chain run alongside each other, joined together by hydrogen bonding between atoms of the polypeptide backbone. Also known as a β -pleated sheet.

binding site A region on the surface of one molecule (usually a protein or nucleic acid) that can interact with another molecule through noncovalent bonding.

biosphere The world of living organisms.

biotin Low-molecular-weight compound used as a coenzyme. Useful technically as a covalent label for proteins, allowing them to be detected by the egg protein avidin, which binds extremely tightly to biotin. (See [Figure 2–63](#).)

bivalent A duplicated chromosome paired with its homologous duplicated chromosome at the beginning of meiosis.

black membrane Artificial planar lipid bilayer membrane.

blastomere One of the cells formed by the cleavage of a fertilized egg.

blastula Early stage of an animal embryo, usually consisting of a hollow ball of cells, before gastrulation begins.

blotting Biochemical technique in which macromolecules separated on an agarose or polyacrylamide gel are transferred to a nylon membrane or sheet of paper, thereby immobilizing them for further analysis. (See **Northern blotting**, **Southern blotting**, **Western blotting**.)

bond energy Strength of the chemical linkage between two atoms, measured by the energy in kilocalories or kilojoules needed to break it.

bright-field microscope The normal light microscope in which the image is obtained by simple transmission of light through the object being viewed.

brush border Dense covering of microvilli on the apical surface of epithelial cells in the intestine and kidney. The microvilli aid absorption by increasing the surface area of the cell.

budding yeast Common name often given to the baker's yeast *Saccharomyces cerevisiae*, a common experimental organism, which divides by budding off a smaller cell.

C terminus *see* **carboxyl terminus**

Ca²⁺/calmodulin-dependent protein kinase (CaM kinase) Protein kinase

whose activity is regulated by the binding of Ca^{2+} -activated calmodulin (Ca^{2+} /calmodulin), and which indirectly mediates the effects of Ca^{2+} by phosphorylation of other proteins.

cadherin A member of a family of proteins that mediates Ca^{2+} -dependent cell–cell adhesion in animal tissues.

caged molecule Organic molecule designed to change into an active form when irradiated with light of a specific wavelength. An example is caged ATP.

calcium pump (Ca^{2+} ATPase) Transport protein in the membrane of the sarcoplasmic reticulum of muscle cells (and elsewhere) that pumps Ca^{2+} out of the cytoplasm into the sarcoplasmic reticulum using the energy of ATP hydrolysis.

calmodulin Ubiquitous calcium-binding protein whose binding to other proteins is governed by changes in intracellular Ca^{2+} concentration. Its binding modifies the activity of many target enzymes and membrane transport proteins.

calorie Unit of heat. One calorie (small "c") is the amount of heat needed to raise the temperature of 1 gram of water by 1°C . A kilocalorie (1000 calories) is the unit used to describe the energy content of foods.

Calvin cycle (Calvin-Benson cycle) Major metabolic pathway by which CO_2 is incorporated into carbohydrate during the second stage of photosynthesis (carbon fixation) in plants. Also called the carbon-fixation cycle.

CAM *see cell adhesion molecule*

CaM kinase *see Ca^{2+} /calmodulin-dependent protein kinase*

CaM-kinase II Multifunctional Ca^{2+} /calmodulin-dependent protein kinase found in all animal cells that undergoes autophosphorylation when activated. It is especially abundant in brain and is thought to have a role in learning and memory in vertebrates.

cAMP *see cyclic AMP*

capacitation Poorly understood process that sperm must go through in the female reproductive tract before they are competent for fertilization.

capsid Protein coat of a virus, formed by the self-assembly of one or more protein subunits into a geometrically regular structure.

carbohydrate General term for sugars and related compounds containing carbon, hydrogen, and oxygen, usually with the empirical formula $(\text{CH}_2\text{O})_n$.

carbon fixation Process by which green plants incorporate carbon atoms from atmospheric carbon dioxide into sugars. The second stage of photosynthesis.

carbon-fixation cycle *see* **Calvin cycle**

carbonyl group Pair of atoms consisting of a carbon atom linked to an oxygen atom by a double bond (C=O).

carboxyl group Carbon atom linked both to an oxygen atom by a double bond and to a hydroxyl group. Molecules containing a carboxyl group are weak acids — **carboxylic acids** ($\text{—C} \begin{array}{l} \text{O} \\ \text{=O} \\ \text{OH} \end{array}$).

carboxyl terminus (C terminus) The end of a polypeptide chain that carries a free α -carbonyl group.

carcinogen Any agent, such as a chemical or a form of radiation, that causes cancer.

carcinogenesis Generation of a cancer.

carcinoma Cancer of epithelial cells. The most common form of human cancer.

cardiac muscle Specialized form of striated muscle found in the heart, consisting of individual heart muscle cells linked together by cell junctions.

carrier protein Membrane transport protein that binds to a solute and transports it across the membrane by undergoing a series of conformational changes.

cartilage Form of connective tissue composed of cells (chondrocytes) embedded in a matrix rich in type II collagen and chondroitin sulfate.

caspase Any of a family of intracellular proteases that are involved in initiating the cellular events of apoptosis.

catabolism General term for the enzyme-catalyzed reactions in a cell by which complex molecules are degraded to simpler ones with release of energy. Intermediates in these reactions are sometimes called catabolites.

catalyst Substance that can lower the activation energy of a reaction, thus increasing its rate.

caveola (caveolae) Invaginations at the cell surface that bud off internally to form pinocytic vesicles. Thought to form from lipid rafts, regions of membrane rich in certain lipids.

CD28 Cell-surface protein on T cells that binds the co-stimulatory B7 protein on "professional" antigen-presenting cells, providing an additional signal required for the activation of a naïve T cell by antigen.

CD4 Co-receptor protein found on helper T cells that binds to class II MHC

molecules outside the antigen-binding site.

CD8 Co-receptor protein found on cytotoxic T cells that binds to class I MHC molecules outside the antigen-binding site.

cdc gene *see* **cell-division-cycle gene**

Cdk inhibitor protein (CKI) Protein that binds to and inhibits cyclin-Cdk complexes, primarily involved in the control of G₁ and S phases.

Cdk-activating kinase (CAK) Protein kinase that phosphorylates Cdks in cyclin-Cdk complexes, activating the Cdk.

Cdk *see* **cyclin-dependent kinase**

cDNA DNA molecule made as a copy of messenger RNA and therefore lacking the introns that are present in genomic DNA. **cDNA clones** represent DNA cloned from cDNA and a collection of such clones, usually representing the genes expressed in a particular cell type or tissue, is a **cDNA library**.

cell adhesion molecule (CAM) Protein on the surface of an animal cell that mediates cell–cell binding or cell–matrix binding.

cell body Main part of a nerve cell that contains the nucleus. The other parts are the axons and dendrites.

cell coat *see* **glycocalyx**

cell cortex Specialized layer of cytoplasm on the inner face of the plasma membrane. In animal cells it is an actin-rich layer responsible for movements of the cell surface.

cell cycle (cell-division cycle) Reproductive cycle of a cell: the orderly sequence of events by which a cell duplicates its contents and divides into two.

cell division Separation of a cell into two daughter cells. In eucaryotic cells it entails division of the nucleus (mitosis) closely followed by division of the cytoplasm (cytokinesis).

cell fate In developmental biology, describes what a particular cell at a given stage of development will normally give rise to.

cell fusion Process in which the plasma membranes of two cells fuse down at the point of contact between them, allowing the two cytoplasms to mingle.

cell junction Specialized region of connection between two cells or between a cell and the extracellular matrix.

cell line Population of cells of plant or animal origin capable of dividing indefinitely in culture.

cell plate Flattened membrane-bounded structure that forms by fusing vesicles in the cytoplasm of a dividing plant cell and is the precursor of the new cell wall.

cell wall Mechanically strong extracellular matrix deposited by a cell outside its plasma membrane. It is prominent in most plants, bacteria, algae, and fungi. Not present in most animal cells.

cell-cycle control system Network of regulatory proteins that governs progression of a eucaryotic cell through the cell cycle.

cell-division-cycle gene (*cdc* gene) Gene that controls a specific step or set of steps in the eucaryotic cell cycle. Originally identified in yeasts.

cell-free system Fractionated cell homogenate that retains a particular biological function of the intact cell, and in which biochemical reactions and cell processes can be more easily studied.

cell-mediated immune response That part of an adaptive immune response in which antigen-specific T cells are activated to perform various functions such as killing infected cells and activating macrophages.

cellularization The formation of cells around each nucleus in a multinucleate cytoplasm, transforming it into a multicellular structure.

cellulose Structural polysaccharide consisting of long chains of covalently linked glucose units. It provides tensile strength in plant cell walls.

centimorgan *see* **genetic map distance**

central lymphoid organ (primary lymphoid organ) Lymphoid organ in which lymphocytes develop. In adult mammals these are the thymus and bone marrow.

central nervous system (CNS) Main information-processing organ of the nervous system. In vertebrates it consists of the brain and spinal cord.

centriole Short cylindrical array of microtubules, closely similar in structure to a basal body. A pair of centrioles is usually found at the center of a centrosome in animal cells.

centromere Constricted region of a mitotic chromosome that holds sister chromatids together. It is also the site on the DNA where the kinetochore forms that captures microtubules from the mitotic spindle.

centrosome cycle Duplication of the centrosome (during interphase) and separation of the two new centrosomes (at the beginning of mitosis), which provides two centrosomes to form the poles of the mitotic spindle.

centrosome Centrally located organelle of animal cells that is the primary microtubule-organizing center and acts as the spindle pole during mitosis. In

most animal cells it contains a pair of centrioles.

CG island Region of DNA with a greater than average density of CG sequences; these regions generally remain unmethylated.

CGN *see cis Golgi network*

channel protein Membrane transport protein that forms an aqueous pore in the membrane through which a specific solute, usually an ion, can pass.

chaperone (molecular chaperone) Protein that helps other proteins avoid misfolding pathways that produce inactive or aggregated polypeptides.

checkpoint Point in the eucaryotic cell-division cycle where progress through the cycle can be halted until conditions are suitable for the cell to proceed to the next stage.

chelate Combine reversibly, usually with high affinity, with a metal ion such as iron, calcium, or magnesium.

chemical group Set of covalently linked atoms, such as a hydroxyl group (–OH) or an amino group (–NH₂), the chemical behavior of which is well characterized.

chemiosmotic coupling Mechanism in which a gradient of hydrogen ions (a pH gradient) across a membrane is used to drive an energy-requiring process, such as ATP production or the rotation of bacterial flagella.

chemokine Small secreted protein that attracts cells, such as white blood cells, to move towards its source. Important in the functioning of the immune system.

chemotaxis Directed movement of a cell or organism towards or away from a diffusible chemical.

chiasma (chiasmata) X-shaped connection visible between paired homologous chromosomes in division I of meiosis, and which represents a site of crossing-over.

chlorophyll Light-absorbing green pigment that plays a central part in photosynthesis in bacteria, plants, and algae.

chloroplast Organelle in green algae and plants that contains chlorophyll and carries out photosynthesis. It is a specialized form of plastid.

cholesterol Lipid molecule with a characteristic four-ring steroid structure that is an important component of the plasma membranes of animal cells. (See [Figure 10–10](#).)

chondrocyte (cartilage cell) Connective-tissue cell that secretes the matrix of cartilage.

chromaffin cell Cell that stores adrenaline in secretory vesicles and secretes it in times of stress when stimulated by the nervous system.

chromatid One copy of a chromosome formed by DNA replication that is still joined at the centromere to the other copy. The two identical chromatids are called sister chromatids.

chromatin Complex of DNA, histones, and nonhistone proteins found in the nucleus of a eucaryotic cell. The material of which chromosomes are made.

chromatography Biochemical technique in which a mixture of substances is separated by charge, size, or some other property by allowing it to partition between a moving phase and a stationary phase. (See **affinity chromatography**, **DNA affinity chromatography**, **high-performance liquid chromatography**.)

chromosomal crossing-over The exchange of DNA between paired homologous chromosomes in division I of meiosis. It is a sign of genetic recombination and the crossovers (chiasmata) are visible in the light microscope. (See [Figure 20–10](#).)

chromosome Structure composed of a very long DNA molecule and associated proteins that carries part (or all) of the hereditary information of an organism. Especially evident in plant and animal cells undergoing mitosis or meiosis, where each chromosome becomes condensed into a compact rodlike structure visible under the light microscope.

chromosome condensation Process by which a chromosome becomes packed up into a more compact structure prior to M phase of the cell cycle.

cilium (cilia) Hairlike extension of a eucaryotic cell containing a core bundle of microtubules and capable of performing repeated beating movements. Cilia are found in large numbers on the surface of many cells, and are responsible for the swimming of many single-celled organisms.

circadian clock Internal cyclical process that produces a particular change in a cell or organism with a period of around 24 hours, for example the sleep-wakefulness cycle in humans.

cis face Face of a Golgi stack at which material enters the organelle. It is adjacent to the *cis* Golgi network.

cis Golgi network (CGN) Network of interconnected cisternae and tubules which receives vesicles from the endoplasmic reticulum and transfers material to the *cis* face of the Golgi apparatus.

cisterna (cisternae) Flattened membrane-bounded compartment, as found in the endoplasmic reticulum or Golgi apparatus.

citric acid cycle (tricarboxylic acid (TCA) cycle, Krebs cycle) Central

metabolic pathway found in aerobic organisms. Oxidizes acetyl groups derived from food molecules to CO₂ and H₂O. In eucaryotic cells it occurs in the mitochondria.

CKI *see* **Cdk inhibitor protein**

class I MHC molecule One of the two classes of MHC molecule. It is present on almost all cell types and presents viral peptides on the surface of virus-infected cells, where they are recognized by cytotoxic T cells. (See [Figure 24–49](#).)

class II MHC molecule One of the two classes of MHC molecule. It is present on "professional" antigen-presenting cells and presents foreign peptides to helper T cells. (See [Figure 24–49](#).)

class switching The change from making one class of immunoglobulin (for example IgM) to making another class (for example IgG) that many B cells undergo during the course of an immune response.

classical pathway A pathway for activating the complement system that is initiated by IgG or IgM antibodies bound to the surface of a microbe.

clathrin Protein that assembles into a polyhedral cage on the cytosolic side of a membrane so as to form a clathrin-coated pit, which buds off by endocytosis to form an intracellular clathrin-coated vesicle.

clathrin-coated pit Region of plasma membrane of animal cells that is coated with the protein clathrin on its cytosolic face. Such regions are continually forming and budding off by endocytosis to form intracellular clathrin-coated vesicles containing extracellular fluid and the materials dissolved in it.

cleavage (1) Physical splitting of a cell into two. (2) Specialized type of cell division seen in many early embryos whereby a large cell becomes subdivided into many smaller cells without growth.

clonal selection theory Theory that explains how the adaptive immune system can respond to millions of different antigens in a highly specific way. From a population of lymphocytes with a vast repertoire of randomly generated antigen specificities, a given foreign antigen activates (selects) only those cells with the corresponding antigen specificity.

clone Population of cells or organisms formed by repeated (asexual) division from a common cell or organism. Also used as a verb: "to clone a gene" means to produce many copies of a gene by repeated cycles of replication.

cloning vector A small DNA molecule, usually derived from a bacteriophage or plasmid, which is used to carry the fragment of DNA to be cloned into the recipient cell, and which enables the DNA fragment to be replicated.

coated vesicle Small membrane-bounded organelle with a cage of proteins

(the coat) on its cytosolic surface. It is formed by the pinching off of a coated region of membrane (**coated pit**). Some coats are made of clathrin, whereas others are made from other proteins.

codon Sequence of three nucleotides in a DNA or messenger RNA molecule that represents the instruction for incorporation of a specific amino acid into a growing polypeptide chain.

coenzyme Small molecule tightly associated with an enzyme that participates in the reaction that the enzyme catalyzes, often by forming a covalent bond to the substrate. Examples include biotin, NAD⁺, and coenzyme A.

coenzyme A Small molecule used in the enzymatic transfer of acyl groups in the cell. (See also **acetyl CoA**.)

cofactor Inorganic ion or coenzyme that is required for an enzyme's activity.

cohesin, cohesin complex Complex of proteins that holds sister chromatids together along their length before their separation.

coiled-coil Especially stable rodlike structure in proteins which is formed by two of these α helices coiled around each other.

collagen fibril Extracellular structure formed by self-assembly of secreted fibrillar collagen subunits. An abundant constituent of the extracellular matrix in many animal tissues.

collagen Fibrous protein rich in glycine and proline that is a major component of the extracellular matrix and connective tissues. Exists in many forms: type I, the most common, is found in skin, tendon, and bone; type II is found in cartilage; type IV is present in basal laminae.

colony-stimulating factor (CSF) General name for the numerous signal molecules that control the differentiation of blood cells.

colorectal tumor Common carcinoma of the epithelium lining the colon and rectum.

combinatorial control Describes the control of a step in a cellular process, such as the initiation of DNA transcription, by a combination of proteins rather than by any individual one.

communicating junction Type of cell junction that allows the passage of chemical or electrical signals from one cell to another.

compartment Regions in the embryo that are formed exclusively from the descendants of a few founder cells; there is no cell movement between compartments once delimited.

complement system System of serum proteins activated by antibody–antigen complexes or by microorganisms. Helps eliminate pathogenic microorganisms

by directly causing their lysis or by promoting their phagocytosis.

complementary DNA *see* **cDNA**

complementary Two nucleic acid sequences are said to be complementary if they can form a perfect base-paired double helix with each other.

complex oligosaccharide Chain of sugars attached to a glycoprotein that is generated by trimming of the original oligosaccharide attached in the endoplasmic reticulum and subsequent addition of further sugars. (See [Figure 13–25](#).)

complex Assembly of molecules that are held together by noncovalent bonds. Protein complexes perform most cell functions.

condensation reaction Chemical reaction in which two molecules are covalently linked through –OH groups with the removal of a molecule of water.

condensin, condensin complex Complex of proteins involved in chromosome condensation prior to mitosis. Target for the M-Cdk.

conditional mutation A mutation that changes a protein or RNA molecule so that its function is altered only under some conditions, such as at an unusually high or an unusually low temperature.

confocal microscope Type of light microscope that produces a clear image of a given plane within a solid object. It uses a laser beam as a pinpoint source of illumination and scans across the plane to produce a two-dimensional 'optical section.'

conformation The spatial arrangement of atoms in three dimensions in a macromolecule such as a protein or nucleic acid.

connective tissue Any supporting tissue that lies between other tissues and consists of cells embedded in a relatively large amount of extracellular matrix. Includes bone, cartilage, and loose connective tissue.

connective-tissue cell Any of the various cell types found in connective tissue, e.g. fibroblasts, cartilage cells (chondrocytes), bone cells (osteoblasts and osteocytes), fat cells (adipocytes) and smooth muscle cells.

connexon Water-filled pore in the plasma membrane formed by a ring of six protein subunits. Part of a gap junction: connexons from two adjoining cells join to form a continuous channel between the two cells.

consensus sequence Average or most typical form of a sequence that is reproduced with minor variations in a group of related DNA, RNA, or protein sequences. The consensus sequence shows the nucleotide or amino acid most often found at each position. The preservation of a consensus implies that the

sequence is functionally important. (See [Figure 6–12](#).)

constitutive secretory pathway Pathway present in all cells by which molecules such as plasma membrane proteins are continually delivered to the plasma membrane from the Golgi apparatus in vesicles that fuse with the plasma membrane. (See also **default pathway**.)

constitutive Produced in constant amount; opposite of regulated.

contact-dependent signaling Cell–cell communication in which the signal molecule remains bound to the signaling cell and only influences cells that physically contact it.

contractile ring Ring containing actin and myosin that forms under the surface of animal cells undergoing cell division and contracts to pinch the two daughter cells apart.

convergent extension Cellular rearrangement within a tissue that causes it to extend in one dimension (e.g. length) and shrink in another (e.g. width).

cooperativity Phenomenon in which the binding of one ligand molecule to a target molecule promotes the binding of successive ligand molecules. Seen in the assembly of large complexes, as well as in enzymes and receptors composed of multiple allosteric subunits, where it sharpens the response to a ligand. (See [Figure 15–22](#).)

cortical granule Specialized secretory vesicle present under the plasma membrane of unfertilized eggs, including those of mammals; after fertilization it is involved in preventing the entry of further sperm.

co-translational Describes import of a protein into the endoplasmic reticulum before the polypeptide chain is completely synthesized.

co-transport (coupled transport) Membrane transport process in which the transfer of one molecule depends on the simultaneous or sequential transfer of a second molecule.

coupled reaction Linked pair of chemical reactions in which the free energy released by one of the reactions serves to drive the other.

covalent bond Stable chemical link between two atoms produced by sharing one or more pairs of electrons.

crista (cristae) (1) (2) One of the folds of the inner mitochondrial membrane. (3) A sensory structure in the inner ear.

critical concentration Concentration of a protein monomer, such as actin or tubulin, that is in equilibrium with the assembled form of the protein (i.e. assembled into actin filaments or microtubules respectively). (See Panel 16–2, pp. 912–913.)

crossing-over *see* **chromosomal crossing-over**

cryoelectron microscopy Electron microscopy technique in which the objects to be viewed, such as macromolecules and viruses, are rapidly frozen.

cryptochrome Flavoprotein responsive to blue light, found in both plants and animals. In animals it is involved in circadian rhythms.

cut-and-paste transposition Type of movement of a transposable element in which it is cut out of the DNA and inserted into a new site by a special transposase enzyme.

cyclic AMP (cAMP) Nucleotide that is generated from ATP by adenylyl cyclase in response to stimulation of many types of cell-surface receptors. cAMP acts as an intracellular signaling molecule by activating cyclic-AMP-dependent kinase (protein kinase A, PKA). It is hydrolyzed to AMP by a phosphodiesterase.

cyclic AMP-dependent protein kinase (protein kinase A, PKA) Enzyme that phosphorylates target proteins in response to a rise in intracellular cyclic AMP.

cyclic GMP Small soluble intracellular signaling molecule formed from GTP by the enzyme guanylyl cyclase in response to photoreceptor stimulation in the retina.

cyclin Protein that periodically rises and falls in concentration in step with the eucaryotic cell cycle. Cyclins activate crucial protein kinases (called a cyclin-dependent protein kinase, or Cdk) and thereby help control progression from one stage of the cell cycle to the next.

cyclin-Cdk complex Protein complexes that are formed periodically during the eucaryotic cell cycle as the level of cyclin increases, and in which the cyclin-dependent kinase (Cdk) becomes partially activated.

cyclin-dependent kinase (Cdk) Protein kinase that has to be complexed with a cyclin protein in order to act. Different Cdk-cyclin complexes trigger different steps in the cell-division cycle by phosphorylating specific target proteins.

cytochrome b-c₁ complex Second of the three electron-driven proton pumps in the respiratory chain. It accepts electrons from ubiquinone.

cytochrome oxidase complex Third of the three electron-driven proton pumps in the respiratory chain. It accepts electrons from cytochrome *c* and generates water using molecular oxygen as an electron acceptor.

cytochrome Colored, heme-containing protein that transfers electrons during cellular respiration and photosynthesis.

cytokine Extracellular signal protein or peptide that acts as a local mediator in cell–cell communication.

cytokine receptor Type of cell-surface receptor whose ligands are cytokines such as interferons, growth hormone and prolactin, and which acts through the Jak-STAT pathway.

cytokinesis Division of the cytoplasm of a plant or animal cell into two, as distinct from the division of its nucleus (which is mitosis)

cytoplasm Contents of a cell that are contained within its plasma membrane but, in the case of eucaryotic cells, outside the nucleus.

cytoskeleton System of protein filaments in the cytoplasm of a eucaryotic cell that gives the cell shape and the capacity for directed movement. Its most abundant components are actin filaments, microtubules, and intermediate filaments.

cytosol Contents of the main compartment of the cytoplasm, excluding membrane-bounded organelles such as endoplasmic reticulum and mitochondria. Originally defined operationally as the cell fraction remaining after membranes, cytoskeletal components, and other organelles have been removed by low-speed centrifugation.

cytotoxic T cell Type of T cell responsible for killing infected cells.

ΔG° *see* **standard free-energy change**

ΔG *see* **free-energy change**

dalton Unit of molecular mass. Approximately equal to the mass of a hydrogen atom (1.66×10^{-24} g).

default pathway Constitutive secretory pathway that automatically delivers material from the Golgi apparatus to the plasma membrane if no other sorting signals are present.

degenerate Not a moral judgment but an adjective that describes multiple states that amount to the same thing: different triplet combinations of nucleotide bases (codons) that code for the same amino acid, for example.

deletion Type of mutation in which a single nucleotide or sequence of nucleotides has been removed from the DNA.

denaturation Dramatic change in conformation of a protein or nucleic acid caused by heating or by exposure to chemicals and usually resulting in the loss of biological function.

dendrite Extension of a nerve cell, typically branched and relatively short, that receives stimuli from other nerve cells.

dendritic cell Cell derived from bone marrow and present in lymphoid and other tissues that is specialized for the uptake of particulate material by phagocytosis and which acts as a "professional" antigen-presenting cell in immune responses.

deoxyribonucleic acid *see* **DNA**

desensitization *see* **adaptation**

desmosome Type of anchoring cell–cell junction, usually formed between two epithelial cells, characterized by dense plaques of protein into which intermediate filaments in the two adjoining cells insert.

detergent Type of small amphipathic molecule that tends to coalesce in water, with its hydrophobic tails buried and its hydrophilic heads exposed. It is widely used to solubilize membrane proteins.

determined In developmental biology, an embryonic cell is said to be determined if it has become committed to a particular specialized path of development. This **determination** reflects a change in the internal character of the cell, and it precedes the much more readily detected process of cell differentiation.

development Succession of changes that take place in an organism as a fertilized egg gives rise to an adult plant or animal.

diacylglycerol Lipid produced by the cleavage of inositol phospholipids in response to extracellular signals. Composed of two fatty acid chains linked to glycerol, it serves as a signaling molecule to help activate protein kinase C.

dideoxy method The standard method of DNA sequencing.

differentiation Process by which a cell undergoes a change to an overtly specialized cell type.

diffraction pattern Pattern set up by wave interference between radiation transmitted or scattered by different parts of an object.

diffusion Net drift of molecules in the direction of lower concentration due to random thermal movement.

diploid Containing two sets of homologous chromosomes and hence two copies of each gene or genetic locus.

diplotene Fourth stage of division I of meiosis, in which chiasmata are first seen.

disaccharide Carbohydrate molecule consisting of two covalently joined monosaccharide units. (See Panel 2–4, p. 116–117.)

dissociation constant (K_d) Measure of the tendency of a complex to

dissociate. For components A and B and the binding equilibrium $A + B \rightleftharpoons AB$, the dissociation constant is given by $[A][B]/[AB]$, and it is smaller the tighter the binding between A and B. (See also **association constant**.)

disulfide bond (–S–S–) Covalent linkage formed between two sulfhydryl groups on cysteines. For extracellular proteins, a common way of joining two proteins together or linking different parts of the same protein. Formed in the endoplasmic reticulum of eucaryotic cells.

division I of meiosis The first cell division of meiosis, in which the members of each pair of (duplicated) homologous chromosomes are segregated to opposite poles of the dividing cell.

division II of meiosis The second cell division of meiosis, in which the chromatids of each duplicated chromosome are segregated to opposite poles of the dividing cell.

DNA (deoxyribonucleic acid) Polynucleotide formed from covalently linked deoxyribonucleotide units. It serves as the store of hereditary information within a cell and the carrier of this information from generation to generation.

DNA affinity chromatography Technique for purifying sequence-specific DNA-binding proteins by their binding to a matrix to which the appropriate DNA fragments are attached.

DNA footprinting Technique for determining the DNA sequence to which a DNA-binding protein binds.

DNA helicase Enzyme that is involved in opening the DNA helix into its single strands for DNA replication.

DNA library Collection of cloned DNA molecules, representing either an entire genome (genomic library) or DNA copies of the messenger RNA produced by a cell (cDNA library).

DNA ligase Enzyme that joins the ends of two strands of DNA together with a covalent bond to make a continuous DNA strand.

DNA methylation Addition of a methyl group to DNA. Extensive methylation of the cytosine base in CG sequences is used in vertebrates to keep genes in an inactive state.

DNA microarray Technique for analyzing the simultaneous expression of large numbers of genes in cells, in which isolated cellular RNA is hybridized to a large array of short DNA probes immobilized on glass slides.

DNA polymerase Enzyme that synthesizes DNA by joining nucleotides together using a DNA template as a guide.

DNA primase Enzyme that synthesizes a short strand of RNA on a DNA template, producing a primer for DNA synthesis.

DNA repair Collective name for those biochemical processes that correct accidental changes in the DNA.

DNA sequencing Determination of the order of nucleotides in a DNA molecule. (See [Figure 8–36](#).)

DNA supercoiling Additional twisting of the DNA helix that occurs in response to the superhelical tension created when, for example, a circular DNA is partly unwound (See [Figure 6–20](#).)

DNA topoisomerase Enzyme that binds to DNA and reversibly breaks a phosphodiester bond in one or both strands, allowing the DNA to rotate at that point. It prevents DNA tangling during replication.

DNA transcription *see* **transcription**

DNA tumor virus A general term for a variety of different DNA viruses that can cause tumors.

DNA-only transposon Type of transposable element that exists as DNA throughout its life cycle. Many types move by cut-and-paste transposition.

domain *see* **protein domain**

dominant negative mutation Mutation that dominantly affects the phenotype by means of a defective protein or RNA molecule that interferes with the function of the normal gene product in the same cell.

dominant In genetics, refers to the member of a pair of alleles that is expressed in the phenotype of the organism while the other allele is not, even though both alleles are present. Opposite of recessive.

dorsal Relating to the back of an animal. Also the upper surface of a leaf, wing, etc.

dorsoventral Describes the axis running from the back to the belly of an animal or from the upper side to the underside of a structure.

double helix The three-dimensional structure of DNA, in which two DNA chains held together by hydrogen bonding between the bases are wound into a helix.

Drosophila melanogaster Species of small fly, commonly called a fruit fly, much used in genetic studies of development.

dynamic instability The property of sudden conversion from growth to shrinkage, and vice versa, in a protein filament such as a microtubule or actin

filament. (See Panel 16–2, pp. 912–913.)

dynamin Cytosolic GTPase that binds to the neck of a clathrin-coated vesicle in the process of budding from the membrane, and which is involved in completing vesicle formation.

dynein Member of a family of large motor proteins that undergo ATP-dependent movement along microtubules. In cilia, dynein forms the side arms in the axoneme that cause adjacent microtubule doublets to slide past one another.

dysplasia A change in cell growth and behavior in a tissue in which the structure becomes disordered.

ectoderm Embryonic tissue that is the precursor of the epidermis and nervous system.

effector cell A cell that carries out the final response or function of a particular process. The main effector cells of the immune system, for example, are activated lymphocytes and phagocytes—the cells involved in destroying pathogens and removing them from the body.

egg The mature female gamete in sexually reproducing organisms. It is usually a large and immobile cell.

elastin Hydrophobic protein that forms extracellular extensible fibres (elastic fibres) that give tissues their stretchability and resilience.

electrochemical gradient The combined influence of a difference in the concentration of an ion on the two sides of the membrane and the electrical charge difference across the membrane (membrane potential). It produces a driving force that causes the ion to move across the membrane.

electrochemical proton gradient The result of a combined pH gradient (proton gradient) and the membrane potential.

electron Negatively charged subatomic particle that generally occupies orbitals surrounding the nucleus in an atom.

electron acceptor Atom or molecule that takes up electrons readily, thereby gaining an electron and becoming reduced.

electron carrier Molecule such as cytochrome *c*, which transfers an electron from a donor molecule to an acceptor molecule.

electron donor Molecule that easily gives up an electron, becoming oxidized in the process.

electron microscope Type of microscope that uses a beam of electrons to create the image.

electron-transport chain Series of electron carrier molecules along which electrons move from a higher to a lower energy level to a final acceptor molecule. The energy released during electron movement can be used to power various processes. Electron-transport chains present in the inner mitochondrial membrane and in the thylakoid membrane of chloroplasts generate a proton gradient across the membrane that is used to drive ATP synthesis.

elongation factor Protein required for the addition of amino acids to growing polypeptide chains on ribosomes.

embryogenesis Development of an embryo from a fertilized egg, or zygote.

embryonic stem cell (ES cell) Cell derived from the inner cell mass of the early mammalian embryo that can give rise to all the cells in the body. It can be grown in culture, genetically modified and inserted into a blastocyst to develop a transgenic animal.

endocrine cell Specialized animal cell that secretes a hormone into the blood. Usually part of a gland, such as the thyroid or pituitary gland.

endocytic-exocytic cycle The processes of endocytosis and exocytosis that, respectively, add and remove plasma membrane from the cell, resulting in no overall change in the cell's surface area and volume.

endocytosis Uptake of material into a cell by an invagination of the plasma membrane and its internalization in a membrane-bounded vesicle. (*See also* **pinocytosis** and **phagocytosis**.)

endoderm Embryonic tissue that is the precursor of the gut and associated organs.

endoplasmic reticulum (ER) Labyrinthine membrane-bounded compartment in the cytoplasm of eucaryotic cells, where lipids are synthesized and membrane-bound proteins and secretory proteins are made.

endosome Membrane-bounded organelle in animal cells that carries materials newly ingested by endocytosis and passes many of them on to lysosomes for degradation.

endothelial cell Flattened cell type that forms a sheet (the endothelium) lining all blood vessels.

enhancer Regulatory DNA sequence to which gene regulatory proteins bind, influencing the rate of transcription of a structural gene that can be many thousands of base pairs away.

entropy Thermodynamic quantity that measures the degree of disorder in a system; the higher the entropy, the greater the disorder.

enveloped virus Virus with a capsid surrounded by a lipid membrane (the envelope), which is derived from the host cell plasma membrane when the

virus buds from the cell.

enzyme Protein that catalyzes a specific chemical reaction.

enzyme-linked receptor Major type of cell-surface receptor in which the cytoplasmic domain either has enzymatic activity itself or is associated with an intracellular enzyme. In both cases enzymatic activity is stimulated by ligand binding to the receptor.

epidermis Epithelial layer covering the outer surface of the body. It has different structures in different animal groups. The outer layer of plant tissue is also called the epidermis.

epimerization Reaction that alters the steric arrangement around one atom, as in a sugar molecule.

epinephrine *see* **adrenaline**

epithelial tissue *see* **epithelium**

epithelium (epithelia) Coherent cell sheet formed from one or more layers of cells covering an external surface or lining a cavity.

epitope *see* **antigenic determinant**

equilibrium constant (K) Ratio of forward and reverse rate constants for a reaction and equal to the association constant. (See [Figure 3–44](#).)

equilibrium State where there is no net change in a system. For example, equilibrium is reached in a chemical reaction when the forward and reverse rates are equal.

ER lumen The space enclosed by the membrane of the endoplasmic reticulum (ER).

ER resident protein Protein that remains in the endoplasmic reticulum (ER) or its membranes and carries out its function there, as opposed to proteins that are present in the ER only in transit.

ER retention signal Short amino acid sequence on a protein that prevents it moving out of the endoplasmic reticulum (ER). Found on proteins that are resident in the ER and function there.

ER signal sequence N-terminal signal sequence that directs proteins to enter the endoplasmic reticulum (ER). It is cleaved off by signal peptidase after entry.

ER *see* **endoplasmic reticulum**

erythrocyte (red blood cell) Small, hemoglobin-containing blood cell of vertebrates that transports oxygen and carbon dioxide to and from tissues.

erythropoietin Growth factor that stimulates the production of red blood cells. It is produced by the kidney and acts on precursor cells in bone marrow.

ES cell *see* **embryonic stem cell**

Escherichia coli (*E. coli*) Rodlike bacterium normally found in the colon of humans and other mammals and widely used in biomedical research.

ester Molecule formed by the condensation reaction of an alcohol group with an acidic group. Phosphate groups usually form esters when linked to a second molecule. (*See* Panel 2–1, 110–111.)

ethyl ($-\text{CH}_2\text{CH}_3$) Hydrophobic chemical group derived from ethane (CH_3CH_3).

eucaryote (eukaryote) Organism composed of one or more cells with a distinct nucleus and cytoplasm. Includes all forms of life except viruses and procaryotes (bacteria and archea).

euchromatin Region of an interphase chromosome that stains diffusely; "normal" chromatin, as opposed to the more condensed heterochromatin.

exocytosis Process by which most molecules are secreted from a eucaryotic cell. These molecules are packaged in membrane-bounded vesicles that fuse with the plasma membrane, releasing their contents to the outside.

exon Segment of a eucaryotic gene that consists of a sequence of nucleotides that will be represented in messenger RNA or the final transfer RNA or ribosomal RNA. In protein-coding genes, exons encode amino acids in the protein. An exon is usually adjacent to a noncoding DNA segment called an intron.

expression vector A virus or plasmid that carries a DNA sequence into a suitable host cell and there directs the synthesis of the protein encoded by the sequence.

expression Production of an observable phenotype by a gene—usually by directing the synthesis of a protein.

extracellular matrix Complex network of polysaccharides (such as glycosaminoglycans or cellulose) and proteins (such as collagen) secreted by cells. Serves as a structural element in tissues and also influences their development and physiology.

facilitated diffusion *see* **passive transport**

FADH_2 (reduced flavin adenine dinucleotide) Activated carrier molecule that is produced by the citric acid cycle.

FAK *see* **focal adhesion kinase**

Fas protein (Fas) Membrane-bound receptor that initiates apoptosis in the receptor-bearing cell after binding to its ligand (Fas ligand).

fat Energy-storage lipid in cells. It is composed of triglycerides—fatty acids esterified with glycerol.

fat cell Connective-tissue cell that produces and stores fat in animals.

fatty acid Compound such as palmitic acid that has a carboxylic acid attached to a long hydrocarbon chain. Used as a major source of energy during metabolism and as a starting point for the synthesis of phospholipids. (See Panel 2–5, pp. 118–119.)

Fc receptor One of a family of receptors specific for the invariant constant region (Fc region) of immunoglobulins (other than IgM and IgD); different Fc receptors are specific for IgG, IgA, IgE and their subclasses.

feedback inhibition Type of regulation of metabolism in which an enzyme acting early in a reaction pathway is inhibited by a late product of that pathway.

fermentation Anaerobic energy-yielding metabolic pathway in which pyruvate produced by glycolysis is converted, for example, into lactate or ethanol, with the conversion of NADH to NAD⁺.

fertilization Fusion of a male and a female gamete (both haploid) to form a diploid zygote, which develops into a new individual.

fibrillar collagen Type of collagen molecule which assembles into rope-like structures. Collagens type I (common in skin), II, III, V and XI are of this type.

fibroblast Common cell type found in connective tissue. Secretes an extracellular matrix rich in collagen and other extracellular matrix macromolecules. Migrates and proliferates readily in wounded tissue and in tissue culture.

fibronectin Extracellular matrix protein that is involved in adhesion of cells to the matrix and the guidance of migrating cells during embryogenesis. Integrins on the cell surface are receptors for fibronectin.

filopodium (filopodia) Thin, spike-like protrusion with an actin filament core, generated on the leading edge of a crawling animal cell.

fission yeast Common name often given to the yeast *Schizosaccharomyces pombe*, a common experimental organism. It divides to give two equal-sized cells.

fixative Chemical reagent such as formaldehyde or osmium tetroxide used to preserve cells for microscopy. Samples treated with these reagents are said to

be "fixed," and the process is called fixation.

flagellum (flagella) Long, whiplike protrusion whose undulations drive a cell through a fluid medium. Eucaryotic flagella are longer versions of cilia. Bacterial flagella are smaller and completely different in construction and mechanism of action.

fluid-phase endocytosis Type of endocytosis in which small vesicles bud off internally from the plasma membrane, carrying extracellular fluid and dissolved material into the cell. (*See also* **pinocytosis**.)

fluorescein Fluorescent dye that fluoresces green when illuminated with blue light or ultraviolet light.

fluorescence microscope Microscope designed to view material stained with fluorescent dyes. Similar to a light microscope but the illuminating light is passed through one set of filters before the specimen, to select those wavelengths that excite the dye, and through another set of filters before it reaches the eye, to select only those wavelengths emitted when the dye fluoresces.

fluorescent dye Molecule that absorbs light at one wavelength and responds by emitting light at another wavelength. The emitted light is of longer wavelength (and hence of lower energy) than the light absorbed.

fluorescent resonance energy transfer (FRET) Technique for monitoring the closeness of two fluorescently labeled molecules (and thus their interaction) in cells.

focal adhesion kinase (FAK) Cytoplasmic tyrosine kinase present at cell-matrix junctions (focal adhesions) in association with the cytoplasmic tails of integrins.

focal adhesion, focal contact (adhesion plaque) A type of anchoring cell junction, forming a small region on the surface of a fibroblast or other cell that is anchored to the extracellular matrix. Attachment is mediated by transmembrane proteins such as integrins, which are linked, through other proteins, to actin filaments in the cytoplasm.

follicle cell One of the cell types that surround a developing oocyte or egg.

free energy (G) The energy that can be extracted from a system to drive reactions. Takes into account changes in both energy and entropy.

free ribosome Ribosome that is free in the cytosol, unattached to any membrane. It is the site of synthesis of all proteins encoded by the nuclear genome other than those destined to enter the endoplasmic reticulum.

free-energy change (ΔG) Change in the free energy during a reaction: the free energy of the product molecules minus the free energy of the starting

molecules. A large negative value of ΔG indicates that the reaction has a strong tendency to occur. (See Panel 2–7, pp. 122–123.)

freeze-fracture electron microscopy Technique for studying membrane structure, in which the membrane of a frozen cell is fractured along the interior of the bilayer, separating it into the two monolayers with the interior faces exposed.

FRET *see* **fluorescent resonance energy transfer**

fungus (fungi) Kingdom of eucaryotic organisms that includes the yeasts, molds, and mushrooms. Many plant diseases and a relatively small number of animal diseases are caused by fungi.

γ -tubulin ring complex (γ TuRC) Protein complex containing γ -tubulin and other proteins that is an efficient nucleator of microtubules.

G *see* **free energy**

G₀ G-"zero" phase. State of withdrawal from the eucaryotic cell-division cycle by entry into a quiescent G₁ phase. A common state for differentiated cells.

G₁ phase Gap 1 phase of the eucaryotic cell-division cycle, between the end of cytokinesis and the start of DNA synthesis.

G₁/S-Cdk Complex formed in vertebrate cells by a G₁/S-cyclin and the corresponding cyclin-dependent kinase (Cdk).

G₁-Cdk Complex formed in vertebrate cells by a G₁-cyclin and the corresponding cyclin-dependent kinase (Cdk).

G₂ phase Gap 2 phase of the eucaryotic cell-division cycle, between the end of DNA synthesis and the beginning of mitosis.

GAG *see* **glycosaminoglycan**

gamete Specialized haploid cell, either a sperm or an egg, serving for sexual reproduction.

ganglion (ganglia) Cluster of nerve cells and associated glial cells located outside the central nervous system.

ganglioside Any glycolipid having one or more sialic acid residues in its structure. Found in the plasma membrane of eucaryotic cells and especially abundant in nerve cells.

gap junction Communicating cell–cell junction that allows ions and small molecules to pass from the cytoplasm of one cell to the cytoplasm of the next.

gastrulation The stage in animal embryogenesis during which the embryo is transformed from a ball of cells to a structure with a gut (a gastrula).

gene activator protein A gene regulatory protein that when bound to its regulatory sequence in DNA activates transcription.

gene control region DNA sequences required to initiate transcription of a given gene and control the rate of initiation.

gene conversion Process by which DNA sequence information can be transferred from one DNA helix (which remains unchanged) to another DNA helix whose sequence is altered. It occurs occasionally during general recombination.

gene regulatory protein General name for any protein that binds to a specific DNA sequence to alter the expression of a gene.

gene repressor protein A gene regulatory protein that prevents the initiation of transcription.

gene Region of DNA that controls a discrete hereditary characteristic, usually corresponding to a single protein or RNA. This definition includes the entire functional unit, encompassing coding DNA sequences, noncoding regulatory DNA sequences, and introns.

general recombination, general genetic recombination Recombination that takes place between two homologous chromosomes (as in meiosis).

general transcription factor Any of the proteins whose assembly around the TATA box is required for the initiation of transcription of most eucaryotic genes.

genetic code Set of rules specifying the correspondence between nucleotide triplets (codons) in DNA or RNA and amino acids in proteins.

genetic map Map of the chromosomes in which the distance of genes relative to each other is determined by the amount of genetic recombination that occurs between them.

genetic recombination *see* **recombination**

genetic screen A search through a large collection of mutants for a mutant with a particular phenotype.

genome The totality of genetic information belonging to a cell or an organism; in particular, the DNA that carries this information.

genomic DNA DNA constituting the genome of a cell or an organism. Often used in contrast to cDNA (DNA prepared by reverse transcription from messenger RNA). **Genomic DNA clones** represent DNA cloned directly from chromosomal DNA, and a collection of such clones from a given genome is a

genomic DNA library.

genomic imprinting Situation where a gene is either expressed or not expressed in the embryo depending on which parent it is inherited from.

genomics The science of studying the DNA sequences and properties of entire genomes.

genotype Genetic constitution of an individual cell or organism.

germ cell Precursor cell that will give rise to gametes.

germ line The lineage of germ cells (which contribute to the formation of a new generation of organisms), as distinct from somatic cells (which form the body and leave no descendants).

GFP *see* **green fluorescent protein**

giga- Prefix denoting 10^9 . (From Greek *gigas*, giant.)

G_i *see* **inhibitory G protein**

glial cell Supporting cell of the nervous system, including oligodendrocytes and astrocytes in the vertebrate central nervous system and Schwann cells in the peripheral nervous system.

globular protein Any protein with an approximately rounded shape. Such proteins are contrasted with highly elongated, fibrous proteins such as collagen.

glucose Six-carbon sugar that plays a major role in the metabolism of living cells. Stored in polymeric form as glycogen in animal cells and as starch in plant cells. (See Panel 2–4, pp. 116–117.)

glutaraldehyde Small reactive molecule with two aldehyde groups that is often used as a cross-linking fixative.

glycerol Small organic molecule that is the parent compound of many small molecules in the cell, including phospholipids.

glycocalyx (cell coat) Carbohydrate-rich layer that forms the outer coat of a eucaryotic cell. Composed of the oligosaccharides linked to intrinsic plasma membrane glycoproteins and glycolipids, as well as glycoproteins and proteoglycans that have been secreted and reabsorbed onto the cell surface.

glycogen Polysaccharide composed exclusively of glucose units used to store energy in animal cells. Large granules of glycogen are especially abundant in liver and muscle cells.

glycolipid Membrane lipid molecule with a sugar residue or oligosaccharide attached to the polar headgroup. (See Panel 2–5, pp. 118–119.)

glycolysis Ubiquitous metabolic pathway in the cytosol in which sugars are incompletely degraded with production of ATP. (Literally, "sugar splitting.")

glycoprotein Any protein with one or more oligosaccharide chains covalently linked to amino-acid side chains. Most secreted proteins and most proteins exposed on the outer surface of the plasma membrane are glycoproteins.

glycosaminoglycan (GAG) Long, linear, highly charged polysaccharide composed of a repeating pair of sugars, one of which is always an amino sugar. Mainly found covalently linked to a protein core in extracellular matrix proteoglycans. Examples include chondroitin sulfate, hyaluronic acid, and heparin.

glycosylation The process of adding one or more sugars to a protein or lipid molecule. (*See also O-linked glycosylation, N-linked glycosylation.*)

glycosylphosphatidylinositol anchor (GPI anchor) Type of lipid linkage by which some membrane proteins are bound to the membrane. It is formed as the proteins travel through the endoplasmic reticulum.

Golgi apparatus (Golgi complex) Membrane-bounded organelle in eucaryotic cells in which proteins and lipids transferred from the endoplasmic reticulum are modified and sorted. It is the site of synthesis of many cell wall polysaccharides in plants and extracellular matrix glycosaminoglycans in animal cells.

GPI anchor *see glycosylphosphatidylinositol anchor*

G-protein *see GTP-binding protein*

G-protein-linked receptor Cell-surface receptor that associates with an intracellular trimeric GTP-binding protein (G protein) after receptor activation by an extracellular ligand. These receptors are seven-pass transmembrane proteins.

G_q Class of receptor-coupled G protein that activates phospholipase C- β and originates the inositol phospholipid signaling pathway.

grana (singular granum) Stacked membrane discs (thylakoids) in chloroplasts that contain chlorophyll and are the site of the light-trapping reactions of photosynthesis.

granulocyte Category of white blood cell distinguished by conspicuous cytoplasmic granules. Includes neutrophils, basophils, and eosinophils.

gray crescent Band of pale pigmentation that appears in the egg of some species of amphibian opposite the site of sperm entry following fertilization. Caused by rotation of the egg cortex and associated pigment granules. Marks the future dorsal side.

green fluorescent protein (GFP) Fluorescent protein isolated from a jellyfish. Widely used as a marker in cell biology.

growth cone Migrating motile tip of a growing nerve cell axon or dendrite.

growth factor Extracellular polypeptide signal molecule that can stimulate a cell to grow or proliferate. Examples are epidermal growth factor (EGF) and platelet-derived growth factor (PDGF). Most growth factors also have other actions.

growth regulator *see* **plant growth regulator**

G_s *see* **stimulatory G protein**

GTP (guanosine 5'-triphosphate) Nucleoside triphosphate produced by phosphorylating GDP (guanosine diphosphate). Like ATP it releases a large amount of free energy on hydrolysis of its terminal phosphate group. It has a special role in microtubule assembly, protein synthesis, and cell signaling.

GTPase Enzyme activity that converts GTP to GDP. Also the common name used for monomeric GTP-binding proteins. (*See* GTP-binding protein.)

GTPase-activating protein (GAP) Protein that binds to a GTP-binding protein and inactivates it by stimulating its GTPase activity so that it hydrolyzes its bound GTP to GDP.

GTP-binding protein, G protein Protein with GTPase activity that binds GTP, which activates the protein. The intrinsic GTPase activity eventually converts the GTP to GDP which inactivates the protein. These GTPases act as molecular switches in, for example, intracellular signaling pathways. One family is composed of three different subunits (heterotrimeric GTP-binding proteins). The members of the other, very large family are monomeric GTP-binding proteins; these are commonly referred to as monomeric GTPases.

guanine nucleotide exchange factor (GEF) Protein that binds to a GTP-binding protein and activates it by stimulating it to release its tightly bound GDP, thereby allowing it to bind GTP in its place.

H⁺ *see* **proton**

haploid Having only one set of chromosomes, as in a sperm cell or a bacterium, as distinct from diploid (having two sets of chromosomes).

heat shock protein (stress-response protein) Protein synthesized in increased amounts in response to an elevated temperature or other stressful treatment, and which usually helps the cell to survive the stress. Prominent examples are hsp60 and hsp70.

heavy chain (H chain) The larger of the two types of polypeptide in an immunoglobulin molecule.

HeLa cell Line of human epithelial cells that grows vigorously in culture. Derived from a human cervical carcinoma.

helix-loop-helix (HLH) DNA-binding structural motif present in many gene regulatory proteins. Should not be confused with the helix-turn-helix.

helper T cell Type of T cell that helps stimulate B cells to make antibodies and activates macrophages to kill ingested microorganisms.

heme Cyclic organic molecule containing an iron atom that carries oxygen in hemoglobin and carries an electron in cytochromes. (See [Figure 14–22](#).)

hemidesmosome Specialized anchoring cell junction between an epithelial cell and the underlying basal lamina.

hemoglobin The major protein in red blood cells that associates with O₂ in the lungs by means of a bound heme group.

hemopoiesis Generation of blood cells, mainly in the bone marrow.

hepatocyte Liver cell.

heterocaryon Cell with two or more genetically different nuclei; produced by the fusion of two or more different cells.

heterochromatin Region of a chromosome that remains unusually condensed chromatin; transcriptionally inactive during interphase.

heterodimer Protein complex composed of two different polypeptide chains.

heterozygote Diploid cell or individual having two different alleles of one or more specified genes.

high-energy bond Covalent bond whose hydrolysis releases an unusually large amount of free energy under the conditions existing in a cell. A group linked to a molecule by such a bond is readily transferred from one molecule to another. Examples include the phosphodiester bonds in ATP and the thioester linkage in acetyl CoA.

high-mannose oligosaccharide Chain of sugars attached to a glycoprotein which contains many mannose residues. It is generated by a trimming of the original mannose-rich oligosaccharide that leaves most of the mannose residues with no subsequent addition of further sugars. (See [Figure 13–26](#).)

high-performance liquid chromatography (HPLC) Type of chromatography that uses columns packed with tiny beads of matrix; the solution to be separated is pushed through under high pressure.

histidine-kinase-associated receptor Type of transmembrane receptor found in the plasma membrane of bacteria, yeast and plant cells, and involved, for

example, in sensing stimuli that cause bacterial chemotaxis. Associated with a histidine protein kinase on its cytoplasmic side.

histone One of a group of small abundant proteins, rich in arginine and lysine, four of which form the nucleosome on the DNA in eucaryotic chromosomes.

HIV Human immunodeficiency virus, the retrovirus that is the cause of AIDS.

HLH *see* **helix-loop-helix**

hnRNP protein (heterogeneous nuclear ribonuclear protein) Any of a group of proteins that assemble on newly synthesized RNA, organizing it into a more compact form.

Holliday junction X-shaped structure observed in DNA undergoing recombination, in which the two DNA molecules are held together at the site of crossing-over, also called a cross-strand exchange.

homeobox Short (180 base pairs long) conserved DNA sequence that encodes a DNA-binding protein motif (homeodomain) famous for its presence in genes that are involved in orchestrating development in a wide range of organisms.

homeodomain DNA-binding domain that defines a class of gene regulatory proteins important in animal development.

homeotic mutation Mutation that causes cells in one region of the body to behave as though they were located in another, causing a bizarre disturbance of the body plan.

homolog (1) One of two or more genes that are similar in sequence as a result of derivation from the same ancestral gene. The term covers both orthologs and paralogs. (2) *See* **homologous chromosome**.

homologous Describes organs or molecules that are similar because of their common evolutionary origin. Specifically it describes similarities in protein or nucleic acid sequence.

homologous chromosome (homolog) One of the two copies of a particular chromosome in a diploid cell, each copy being derived from a different parent.

homozygote Diploid cell or organism having two identical alleles of a specified gene or set of genes.

hormone Signal molecule secreted by an endocrine cell into the bloodstream, which can then carry it to distant target cells.

housekeeping gene Gene serving a function required in all the cell types of an organism, regardless of their specialized role.

Hox complex Two tightly linked clusters of genes in *Drosophila* (the bithorax and Antennapedia complexes) that control the differences between the

different segments of the body. Homologous Hox complexes are found in other animals, where they also determine pattern along the anteroposterior axis.

HPLC *see* **high-performance liquid chromatography**

hybridization In molecular biology, the process whereby two complementary nucleic acid strands form a double helix. Forms the basis of a powerful technique for detecting specific nucleotide sequences.

hybridoma Cell line used in the production of monoclonal antibodies. Obtained by fusing antibody-secreting B cells with cells of a lymphocyte tumor.

hydrocarbon Compound that has only carbon and hydrogen atoms. (See Panel 2-1, p 110-111.)

hydrogen bond Noncovalent bond in which an electropositive hydrogen atom is partially shared by two electronegative atoms.

hydrolysis (adjective hydrolytic) Cleavage of a covalent bond with accompanying addition of water, $-H$ being added to one product of the cleavage and $-OH$ to the other.

hydronium ion (H_3O) Water molecule associated with an additional proton.

hydrophilic Describes a polar molecule or part of a molecule that forms enough energetically favorable interactions with water molecules to dissolve readily in water. (Literally, "water loving.")

hydrophobic (lipophilic) Describes a nonpolar molecule or part of a molecule that cannot form energetically favorable interactions with water molecules and therefore does not dissolve in water. (Literally, "water hating.")

hydrophobic force Force exerted by the hydrogen-bonded network of water molecules that brings two nonpolar surfaces together by excluding water between them.

hydroxyl ($-OH$) Chemical group consisting of a hydrogen atom linked to an oxygen, as in an alcohol.

hypertonic Describes any medium with a sufficiently high concentration of solutes to cause water to move out of a cell due to osmosis.

hypervariable region Any of three small regions within the variable region of an immunoglobulin light or heavy chain that show the highest variability from molecule to molecule. These regions determine the specificity of the antigen-binding site.

hypotonic Describes any medium with a sufficiently low concentration of solutes to cause water to move into a cell due to osmosis.

IAP family Intracellular protein inhibitors of apoptosis.

Ig *see* **immunoglobulin**

Ig superfamily Large family of proteins that contain immunoglobulin domains or immunoglobulin-like domains. Most are involved in cell-cell interactions or antigen recognition.

image processing Computer treatment of images gained from microscopy that reveal information not immediately visible to the eye.

imaginal disc Group of cells that are set aside in the *Drosophila* embryo and which will develop into an adult structure, e.g. eye, leg, wing.

immature secretory vesicle Secretory vesicle that appears to have just pinched off the Golgi stack. Its structure resembles that of a cisterna of the *trans* Golgi network.

immortalization Production of a cell line capable of an unlimited number of cell divisions. Can be the result of a chemical or viral transformation or of fusion of the original cells with cells of a tumor line.

immune response Response made by the immune system when a foreign substance or microorganism enters its body. (*See also* **innate immune response, adaptive immune response, primary immune response, secondary immune response.**)

immune system Population of lymphocytes and other white blood cells in the vertebrate body that defends it against infection.

immunoglobulin (Ig) An antibody molecule. Higher vertebrates have five classes of immunoglobulin—IgA, IgD, IgE, IgG, and IgM—each with a different role in the immune response.

immunoglobulin domain (Ig domain) Characteristic protein domain of about 100 amino acids that is found in immunoglobulin light and heavy chains. Similar domains, known as immunoglobulin-like (Ig-like) domains, are present in many other proteins involved in cell–cell interactions and antigen recognition and define the Ig superfamily.

immunogold electron microscopy Electron microscopy technique in which cellular structures or molecules of interest are labeled with antibodies tagged with electron-dense gold particles. These show up as black spots on the image.

immunological memory Long-lived state that follows a primary immune response to many antigens, in which subsequent encounter with that antigen will provoke a rapid secondary immune response.

immunoprecipitation Use of a specific antibody to draw the corresponding protein antigen out of solution. The technique can identify complexes of

interacting proteins in cell extracts by using an antibody specific for one of the proteins to precipitate the complex.

in situ hybridization Technique in which a single-stranded RNA or DNA probe is used to locate a gene or a messenger RNA molecule in a cell or tissue by hybridization.

in vitro Term used by biochemists to describe a process taking place in an isolated cell-free extract. Also used by cell biologists to refer to cells growing in culture (*in vitro*), as opposed to in an organism (*in vivo*). (Latin for "in glass.")

in vivo In an intact cell or organism. (Latin for "in life.")

induction In developmental biology, a change in the developmental fate of one tissue caused by an interaction with another tissue. Such an interaction is called an **inductive interaction**.

inflammatory response Local response of a tissue to injury or infection—characterized by tissue redness, swelling, heat, and pain. Caused by invasion of white blood cells, which release various local mediators such as histamine.

inhibitor of apoptosis family *see* **IAP family**

inhibitory G protein (G_i) G protein that can regulate ion channels and inhibit the enzyme adenylyl cyclase.

inhibitory neurotransmitter Neurotransmitter that opens transmitter-gated Cl^- or K^+ channels in the postsynaptic membrane of a nerve or muscle cell and thus tends to inhibit the generation of an action potential.

initiation factor Protein that promotes the proper association of ribosomes with messenger RNA and is required for the initiation of protein synthesis.

initiator tRNA Special tRNA that initiates translation. It always carries the amino acid methionine.

innate immune response Immune response (of both vertebrates and invertebrates) to a pathogen that involves the pre-existing defenses of the body—the **innate immune system**—such as barriers formed by skin and mucosa, antimicrobial molecules and phagocytes. Such a response is not specific for the pathogen.

inner membrane The innermost of two membranes surrounding an organelle. In the mitochondrion, it encloses the matrix and contains the respiratory electron transport chains.

inner nuclear membrane The innermost of the two nuclear membranes. It contains binding sites for chromatin and the nuclear lamina on its internal face.

inositol phospholipids (phosphoinositides) One of a family of lipids containing phosphorylated inositol derivatives. Although minor components of the plasma membrane, they are important in signal transduction in eucaryotic cells. (See [Figure 15–34](#).)

insulator element DNA sequence that prevents a gene regulatory protein bound to DNA in the control region of one gene from influencing the transcription of adjacent genes.

insulin Polypeptide hormone that is secreted by β cells in the pancreas and helps regulate glucose metabolism in animals.

integral membrane protein Protein that is held tightly in a membrane and can only be removed by treatments that disrupt the lipid bilayer.

integrin Member of a large family of transmembrane proteins involved in the adhesion of cells to the extracellular matrix and to each other.

intercalary regeneration Type of regeneration that fills in the missing tissues when two mismatched parts of a structure are grafted together.

interferon- γ (IFN- γ) Cytokine secreted by certain types of T cells after activation, and which enhances the anti-viral response and macrophage activation.

interleukin Secreted peptide or protein that mainly mediates local interactions between white blood cells (leucocytes) during inflammation and immune responses.

intermediate filament Fibrous protein filament (about 10 nm in diameter) that forms ropelike networks in animal cells. One of the three most prominent types of cytoskeletal filaments. (See [Panel 16–1](#), p. 909.)

intermembrane space (1) The subcompartment formed between the inner and outer mitochondrial membranes. (2) The corresponding compartment in a chloroplast.

internal membrane Eucaryotic cell membrane other than the plasma membrane. The membranes of the endoplasmic reticulum and the Golgi apparatus are examples.

interphase Long period of the cell cycle between one mitosis and the next. Includes G_1 phase, S phase, and G_2 phase.

intracellular signaling protein Protein that relays a signal as part of an intracellular signaling pathway. It may either activate the next protein in the pathway or generate a small intracellular mediator.

intron Noncoding region of a eucaryotic gene that is transcribed into an RNA

molecule but is then excised by RNA splicing during production of the messenger RNA or other functional structural RNA.

inversion Type of mutation in which a segment of chromosome is inverted.

ion channel Transmembrane protein complex that forms a water-filled channel across the lipid bilayer through which specific inorganic ions can diffuse down their electrochemical gradients.

ion An atom that has either gained or lost electrons to acquire a charge; for example Na^+ and Cl^- .

ionic bond Cohesion between two atoms, one with a positive charge, the other with a negative charge. One type of noncovalent bond.

ionophore Small hydrophobic molecule that dissolves in lipid bilayers and increases their permeability to specific inorganic ions.

iron-sulfur center Electron-transporting group consisting of either two or four iron atoms bound to an equal number of sulfur atoms, found in a class of electron-transport proteins.

isoelectric point The pH at which a charged molecule in solution has no net electric charge and therefore does not move in an electric field.

isomers Molecules that are formed from the same atoms in the same chemical linkages but have different three-dimensional conformations. (See Panel 2–4, pp. 116–117.)

isoprenoid (polyisoprenoid) Member of a large family of lipid molecules with a carbon skeleton based on multiple five-carbon isoprene units. Examples include retinoic acid and dolichol.

isotope One of a number of forms of an atom that differ in atomic weight but have the same number of protons and electrons, and therefore the same chemistry. May be either stable or radioactive.

Jak-STAT signaling pathway Rapid signaling pathway by which some extracellular signals (for example interferon) activate gene expression. Involves cell-surface receptors and cytoplasmic Janus kinases (Jaks) plus signal transducers and activators of transcription (STATs).

joule Standard unit of energy in the meter-kilogram system. One joule is the energy delivered in one second by a one-watt power source. Approximately equal to 0.24 calories.

K *see* **equilibrium constant**

K^+ leak channel A K^+ -transporting ion channel in the plasma membrane of animal cells that remains open even in a "resting" cell.

karyotype Full set of chromosomes of a cell arranged with respect to size, shape, and number.

K_a *see* **affinity constant**

keratin Member of the family of proteins that form keratin intermediate filaments, mainly in epithelial cells. Specialized keratins are found in hair, nails, and feathers.

ketone Organic molecule containing a carbonyl group linked to two alkyl groups.

kilo-Prefix denoting 10³.

kilocalorie (kcal) Unit of heat energy equal to 1000 calories. Often used to express the energy content of food or molecules: bond strengths, for example, are measured in kcal/mole. An alternative unit in wide use is the kilojoule, equal to 0.24 kcal.

kilojoule Standard unit of energy equal to 1000 joules, or 0.24 kilocalories.

kinesin One type of motor protein that uses the energy of ATP hydrolysis to move along a microtubule.

kinetochore Complex structure formed from proteins on a mitotic chromosome to which microtubules attach and which plays an active part in the movement of chromosomes to the poles. The kinetochore forms on the part of the chromosome known as the centromere.

kinetochore microtubule In a mitotic or meiotic spindle, a microtubule with one end attached to the kinetochore on a chromosome.

Krebs cycle *see* **citric acid cycle**

label Chemical group, radioactive atom or fluorescent dye added to a molecule in order to follow its progress through a biochemical reaction or to locate it spatially. Also, as a verb, to add such a group or atom to a cell or molecule.

lagging strand One of the two newly synthesized strands of DNA found at a replication fork. The lagging strand is made in discontinuous lengths that are later joined covalently.

lambda bacteriophage (γ bacteriophage) Virus that infects *E. coli*. Widely used as a DNA cloning vector

lamellipodium (lamellipodia) Flattened, sheetlike protrusion supported by a meshwork of actin filaments, which is extended at the leading edge of a crawling animal cell.

laminin Extracellular matrix protein found in basal laminae, where it forms a

sheetlike network.

lamin *see* **nuclear lamin**

lampbrush chromosome Paired chromosome in meiosis in immature amphibian eggs, in which the chromatin forms large stiff loops extending out from the linear axis of the chromosome.

leading strand One of the two newly synthesized strands of DNA found at a replication fork. The leading strand is made by continuous synthesis in the 5'-to-3' direction.

lectin Protein that binds tightly to a specific sugar. Abundant lectins from plant seeds are often used as affinity reagents to purify glycoproteins or to detect them on the surface of cells.

leptotene The first phase of division I of meiosis, in which the paired duplicated homologous chromosomes condense and become visible in the light microscope.

lethal mutation A mutation that causes the death of the cell or the organism that contains it.

leucine zipper Structural motif seen in many DNA-binding proteins in which two α helices from separate proteins are joined together in a coiled-coil (rather like a zipper), forming a protein dimer.

leucine-rich repeat protein (LRR protein) Common type of receptor serine/threonine kinase in plants. Characterized by a tandem array of leucine-rich repeat sequences in the extracellular portion.

leucocyte *see* **white blood cell**

leukemia Cancer of white blood cells.

ligand Any molecule that binds to a specific site on a protein or other molecule. (From Latin *ligare*, to bind.)

ligase Enzyme that joins together (ligates) two molecules in an energy-dependent process. DNA ligase, for example, joins two DNA molecules together end to end through phosphodiester bonds.

light chain One of the smaller polypeptides of a multisubunit protein such as myosin or immunoglobulin. Abbreviated as **L chain** in immunoglobulins.

lineage analysis Tracing the ancestry of individual cells in a developing embryo.

linkage (1) Mutual effect of the binding of one ligand on the binding of another that is a central feature of the behavior of all allosteric proteins. (2) Co-inheritance of two genetic loci that lie near each other on the same

chromosome. The closer together the two loci, that is, the greater the linkage, the lower the frequency of recombination between them.

lipase Enzyme that catalyzes the cleavage of fatty acids from the glycerol moiety of a triglyceride.

lipid Organic molecule that is insoluble in water but tends to dissolve in nonpolar organic solvents. A special class, the phospholipids, forms the structural basis of biological membranes.

lipid bilayer Thin bimolecular sheet of mainly phospholipid molecules that forms the core structure of all cell membranes. The two layers of lipid molecules are packed with their hydrophobic tails pointing inward and their hydrophilic heads outward, exposed to water.

lipid raft Small region of the plasma membrane enriched in sphingolipids and cholesterol.

lipophilic *see* **hydrophobic**

liposome Artificial phospholipid bilayer vesicle formed from an aqueous suspension of phospholipid molecules.

local mediator Secreted signal molecule that acts at short range on adjacent cells.

locus In genetics, the position of a gene on a chromosome. Different alleles of the same gene all occupy the same locus.

long-term potentiation Long-lasting increase (days to weeks) in the sensitivity of certain synapses in the hippocampus. Induced by a short burst of repetitive firing in the presynaptic neurons.

low-density lipoprotein (LDL) Large complex composed of a single protein molecule and many esterified cholesterol molecules, together with other lipids. The form in which cholesterol is transported in the blood and taken up into cells.

LTP *see* **long-term potentiation**

lumen Cavity enclosed by an epithelial sheet (in a tissue) or by a membrane (in a cell).

lymph Colorless fluid derived from blood by filtration through capillary walls. Carries lymphocytes in a special system of ducts and vessels—the lymphatic vessels.

lymphocyte Type of white blood cell responsible for the specificity of adaptive immune responses. There are two main types: B cells, which produce antibody, and T cells, which interact directly with other effector cells of the immune system and with infected cells. T cells develop in the thymus and are

responsible for cell-mediated immunity. B cells develop in the bone marrow in mammals and are responsible for the production of circulating antibodies.

lymphoid organ Organs involved in the production or function of lymphocytes, such as thymus, spleen, lymph nodes, and tonsils.

lysis Rupture of a cell's plasma membrane, leading to the release of cytoplasm and the death of the cell.

lysogeny State of a bacterium in which it carries the DNA of an inactive virus integrated into its genome. The virus can subsequently be activated to replicate and lyse the cell.

lysosome Membrane-bounded organelle in eucaryotic cells containing digestive enzymes, which are typically most active at the acid pH found in the lumen of lysosomes.

lysozyme Enzyme that catalyzes the cutting of polysaccharide chains in the cell walls of bacteria.

M phase Period of the eucaryotic cell cycle during which the nucleus and cytoplasm divide.

M6P *see* **mannose 6-phosphate**

macromolecule Molecule such as a protein, nucleic acid, or polysaccharide with a molecular mass greater than a few thousand daltons.

macrophage Phagocytic cell derived from blood monocytes, typically resident in most tissues. It has both scavenger and antigen-presenting functions in immune responses.

major histocompatibility complex (MHC) Complex of highly polymorphic genes in vertebrates. They code for a large family of cell-surface glycoproteins (MHC molecules) that bind peptide fragments of foreign proteins and present them to T cells to induce an immune response. (*See* [Figure 24–50](#).)

malaria Potentially fatal human disease caused by the protozoan parasite *Plasmodium*, which is transmitted by the bite of an infected mosquito.

malignant Describes tumors and tumor cells that are invasive and/or able to undergo metastasis. A malignant tumor is a cancer.

mannose 6-phosphate (M6P) Unique marker attached to the oligosaccharides on some glycoproteins destined for lysosomes.

map unit *see* **genetic map distance**

MAP *see* **microtubule-associated protein**

MAP-kinase (mitogen-activated protein kinase) Protein kinase that

performs a crucial step in relaying signals from the plasma membrane to the nucleus. Turned on by a wide range of proliferation- or differentiation-inducing signals.

mating-type locus (MAT locus) In budding yeast, the locus that determines the mating type (α or a) of the haploid yeast cell.

matrix space (1) Central subcompartment of a mitochondrion, bounded by the inner mitochondrial membrane. (2) The corresponding compartment in a chloroplast, which is more commonly known as the stroma.

M-Cdk *see* **M-phase Cdk**

Mcm proteins Proteins in the eucaryotic cell that bind to origin recognition complexes in DNA in early G_1 and are involved in forming the pre-replicative complex.

M-cyclin Type of cyclin found in all eucaryotic cells that promotes the events of mitosis.

MDR protein *see* **multidrug resistance protein**

mega- Prefix denoting 10^6 . (From Greek *megas*, huge, powerful.)

megakaryocyte Large myeloid cell with a multilobed nucleus that remains in the bone marrow when mature. It buds off platelets from long cytoplasmic processes.

meiosis Special type of cell division by which eggs and sperm cells are produced. It comprises two successive nuclear divisions with only one round of DNA replication, which produces four haploid daughter cells from an initial diploid cell.

melanocyte Cell that produces the dark pigment melanin. Responsible for the pigmentation of skin and hair.

membrane The lipid bilayer plus associated proteins that encloses all cells and, in eucaryotic cells, many organelles as well.

membrane-bound ribosome Ribosome attached to the cytosolic face of the endoplasmic reticulum. The site of synthesis of proteins that enter the endoplasmic reticulum.

membrane channel Transmembrane protein complex that allows inorganic ions or other small molecules to diffuse passively across the lipid bilayer.

membrane potential Voltage difference across a membrane due to a slight excess of positive ions on one side and of negative ions on the other. A typical membrane potential for an animal cell plasma membrane is -60 mV (inside negative relative to the surrounding fluid).

membrane protein Protein that is normally closely associated with a cell membrane. (See [Figure 10–17](#).)

membrane transport Movement of molecules across a membrane mediated by a membrane transport protein.

membrane transport protein Membrane protein that mediates the passage of ions or molecules across a membrane. Examples are ion channels and carrier proteins.

meristem An organized group of dividing cells whose derivatives give rise to the tissues and organs of a flowering plant. Key examples are the apical meristems at the tips of shoots and roots.

mesenchyme Immature, unspecialized form of connective tissue in animals, consisting of cells embedded in a thin extracellular matrix.

mesoderm Embryonic tissue that is the precursor to muscle, connective tissue, skeleton and many of the internal organs.

messenger RNA (mRNA) RNA molecule that specifies the amino acid sequence of a protein. Produced by RNA splicing (in eucaryotes) from a larger RNA molecule made by RNA polymerase as a complementary copy of DNA. It is translated into protein in a process catalyzed by ribosomes.

metabolism The sum total of the chemical processes that take place in living cells.

metaphase Stage of mitosis at which chromosomes are firmly attached to the mitotic spindle at its equator but have not yet segregated toward opposite poles.

metaphase plate Imaginary plane at right angles to the mitotic spindle and midway between the spindle poles; the plane in which chromosomes are positioned at metaphase.

metaplasia A change in the pattern of cell differentiation in a tissue.

metastasis Spread of cancer cells from their site of origin to other sites in the body.

methyl ($-\text{CH}_3$) Hydrophobic chemical group derived from methane (CH_4).

MHC molecule One of a large family of ubiquitous cell-surface glycoproteins encoded by genes of the major histocompatibility complex (MHC). They bind peptide fragments of foreign antigens and present them to T cells to induce an immune response. (See also **class I MHC molecule**, **class II MHC molecule**.)

MHC *see* **major histocompatibility complex**

micro- Prefix denoting 10^{-6} .

microelectrode, micropipette Piece of fine glass tubing pulled to an even finer tip. Used to penetrate a cell to study its physiology or to inject electric current or molecules.

microfilament *see* **actin filament**

micrograph Photograph of an image seen through a microscope. May be either a light micrograph or an electron micrograph depending on the type of microscope employed.

microinjection Injection of molecules into a cell using a micropipette.

micron (μm or micrometer) Unit of measurement often applied to cells and organelles. Equal to 10^{-6} meter or 10^{-4} centimeter.

micropipette *see* **microelectrode**

microsome Small vesicle that is derived from fragmented endoplasmic reticulum produced when cells are homogenized.

microtubule Long hollow cylindrical structure composed of the protein tubulin. It is one of the three major classes of filaments of the cytoskeleton. (*See* Panel 16–1, p. 909.)

microtubule-associated protein (MAP) Any protein that binds to microtubules and modifies their properties. Many different kinds have been found, including structural proteins, such as MAP-2, and motor proteins, such as dynein.

microtubule-organizing center (MTOC) Region in a cell, such as a centrosome or a basal body, from which microtubules grow.

microvillus (microvilli) Thin cylindrical membrane-covered projection on the surface of an animal cell containing a core bundle of actin filaments. Present in especially large numbers on the absorptive surface of intestinal epithelial cells.

midbody Structure formed at the end of cleavage that can persist for some time as a tether between the two daughter cells in animals.

milli- Prefix denoting 10^{-3} .

minus end The end of a microtubule or actin filament at which the addition of monomers occurs least readily; the "slow-growing" end of the microtubule or actin filament. The minus end of an actin filament is also known as the pointed end. (*See* Panel 16–2, pp. 912–913.)

mismatch repair DNA repair process that corrects mismatched nucleotides inserted during DNA replication. A short stretch of newly synthesized DNA including the mismatched nucleotide is removed and replaced with the correct

sequence with reference to the template strand.

mitochondrial precursor protein Mitochondrial protein encoded by a nuclear gene, synthesized in the cytosol, and subsequently transported into mitochondria.

mitochondrion (mitochondria) Membrane-bounded organelle, about the size of a bacterium, that carries out oxidative phosphorylation and produces most of the ATP in eucaryotic cells.

mitogen An extracellular substance, such as a growth factor, that stimulates cell proliferation.

mitogen-activated protein kinase *see* **MAP-kinase**

mitosis Division of the nucleus of a eucaryotic cell, involving condensation of the DNA into visible chromosomes, and separation of the duplicated chromosomes to form two identical sets. (From Greek *mitos*, a thread, referring to the threadlike appearance of the condensed chromosomes.)

mitotic chromosome Highly condensed duplicated chromosome with the two new chromosomes still held together at the centromere as sister chromatids.

mitotic spindle Array of microtubules and associated molecules that forms between the opposite poles of a eucaryotic cell during mitosis and serves to move the duplicated chromosomes apart.

model organism A species, such as *Drosophila melanogaster* or *Escherichia coli*, that has been studied intensively over a long period and thus serves as a "model" of the biology of a particular type of organism.

module In proteins or nucleic acids, a unit of structure or function that is found in a variety of different contexts in different molecules.

molar Describes a solution with a concentration of 1 mole of a substance dissolved in 1 liter of solution (abbreviated as 1 M).

mole X grams of a substance, where X is its relative molecular mass (molecular weight). A mole consists of 6×10^{23} molecules of the substance.

molecular chaperone *see* **chaperone**

molecular weight Numerically, the same as the relative molecular mass of a molecule expressed in daltons. For example, a protein of relative molecular mass 20,000 has a molecular weight of 20,000.

molecule Group of atoms joined together by covalent bonds.

monoclonal antibody Antibody secreted by a hybridoma clone. Because each such clone is derived from a single B cell, all of the antibody molecules produced are identical.

monocyte Type of white blood cell that leaves the bloodstream and matures into a macrophage in tissues.

monomer Small molecular building block that can serve as a subunit, being linked to others of the same type to form a larger molecule (a polymer).

monosaccharide Simple sugar with the general formula $(\text{CH}_2\text{O})_n$, where $n = 3$ to 8.

morphogen Signal molecule that can impose a pattern on a field of cells by causing cells in different places to adopt different fates.

mosaic In developmental biology, an organism made of a mixture of cells with different genotypes.

motif Element of structure or pattern that recurs in many contexts. Specifically, a small structural domain that can be recognized in a variety of proteins.

motor protein Protein that uses energy derived from nucleoside triphosphate hydrolysis to propel itself along a protein filament or another polymeric molecule.

M-phase Cdk (M-Cdk) Complex formed in vertebrate cells by an M-cyclin and the corresponding cyclin-dependent kinase (Cdk).

mRNA *see* messenger RNA

MTOC *see* microtubule-organizing center

multidrug resistance protein (MDR protein) Type of ABC transporter protein that can pump hydrophobic drugs (such as some anti-cancer drugs) out of the cytoplasm of eucaryotic cells.

multipass transmembrane protein Membrane protein in which the polypeptide chain crosses the lipid bilayer more than once.

mutant Organism in which a mutation has occurred that makes it different from wild-type or from the 'normal' extent of variation in the population.

mutation rate The rate at which observable changes occur in a DNA sequence.

mutation Heritable change in the nucleotide sequence of a chromosome.

myelin sheath Insulating layer of specialized cell membrane wrapped around vertebrate axons. Produced by oligodendrocytes in the central nervous system and by Schwann cells in the peripheral nervous system.

myeloid cell Any white blood cell other than lymphocytes.

myoblast Mononucleated, undifferentiated muscle precursor cell. A skeletal muscle cell is formed by the fusion of multiple myoblasts.

myoepithelial cell Type of unstriated muscle cell found in epithelia, e.g. in the iris of the eye and in glandular tissue.

myofibril Long, highly organized bundle of actin, myosin, and other proteins in the cytoplasm of muscle cells that contracts by a sliding filament mechanism.

N terminus *see* **amino terminus**

Na⁺-K⁺ pump (Na⁺-K⁺ ATPase) Transmembrane carrier protein found in the plasma membrane of most animal cells that pumps Na⁺ out of and K⁺ into the cell, using energy derived from ATP hydrolysis.

NAD⁺ (nicotine adenine dinucleotide) Activated carrier that participates in an oxidation reaction by accepting a hydride ion (H⁻) from a donor molecule. The **NADH** formed is an important carrier of electrons for oxidative phosphorylation.

NADH dehydrogenase complex First of the three electron-driven proton pumps in the mitochondrial respiratory chain. It accepts electrons from NADH.

NADP⁺ (nicotine adenine dinucleotide phosphate) Activated carrier closely related to NAD⁺ that is used extensively in biosynthetic, rather than catabolic, pathways. The reduced form is **NADPH**.

nano- Prefix denoting 10⁻⁹.

nanometer (nm) Unit of length commonly used to measure molecules and cell organelles. 1 nm = 10⁻³ micrometer (μm) = 10⁻⁹ meter.

natural killer cell (NK cell) Cytotoxic cell of the innate immune system that can kill virus-infected cells.

N-CAM *see* **neural cell adhesion molecule**

negative control Type of control of gene expression in which the active DNA-binding form of the regulatory protein turns the gene off.

negative staining Staining technique for use in the electron microscope in which a reverse, or negative, image of the object is created.

Nernst equation Quantitative expression that relates the equilibrium ratio of concentrations of an ion on either side of a permeable membrane to the voltage difference across the membrane. (See Panel 11-2, p. 634.)

nerve cell *see* **neuron**

neural cell adhesion molecule (N-CAM) Cell adhesion molecule of the immunoglobulin superfamily, expressed by many cell types including most nerve cells. It mediates Ca^{2+} -independent cell-cell attachment in vertebrates.

neural tube Tube of ectoderm that will form the brain and spinal cord in a vertebrate embryo.

neurite Long process growing from a nerve cell in culture. A generic term that does not specify whether the process is an axon or a dendrite.

neurofilament Type of intermediate filament found in nerve cells.

neuromuscular junction Specialized chemical synapse between an axon terminal of a motor neuron and a skeletal muscle cell.

neuron (nerve cell) Cell with long processes specialized to receive, conduct, and transmit signals in the nervous system.

neuropeptide Peptide secreted by neurons as a signaling molecule either at synapses or elsewhere.

neurotransmitter Small signal molecule secreted by the presynaptic nerve cell at a chemical synapse to relay the signal to the postsynaptic cell. Examples include acetylcholine, glutamate, GABA, glycine, and many neuropeptides.

neutron Uncharged subatomic particle that forms part of an atomic nucleus.

neutrophil White blood cell that is specialized for the uptake of particulate material by phagocytosis and which enters tissues that become infected or inflamed.

nicotine adenine dinucleotide phosphate *see* NADP^+

nicotine adenine dinucleotide *see* NAD^+

nitric oxide (NO) Gaseous signal molecule in both animals and plants. In animals it regulates smooth muscle contraction, for example; in plants it is involved in responses to injury or infection.

nitrogen cycle The natural circulation of nitrogen between molecular nitrogen in the atmosphere, inorganic molecules in the soil, and organic molecules in living organisms.

nitrogen fixation Biochemical process carried out by certain bacteria that reduces atmospheric nitrogen (N_2) to ammonia, leading eventually to various nitrogen-containing metabolites.

nitrogenase complex Complex of enzymes in nitrogen-fixing bacteria that catalyzes the reduction of atmospheric N_2 to ammonia.

NK cell *see* **natural killer cell**

N-linked oligosaccharide Chain of sugars attached to a protein through the NH₂ group of the side chain of an asparagine residue.

NMR (nuclear magnetic resonance) Resonant absorption of electromagnetic radiation at a specific frequency by atomic nuclei in a magnetic field, due to flipping of the orientation of their magnetic dipole moments. The NMR spectrum provides information about the chemical environment of the nuclei. Two-dimensional NMR is used widely to determine the three-dimensional structure of small proteins.

nm *see* **nanometer**

noncovalent attraction Chemical bond in which, in contrast to a covalent bond, no electrons are shared. Noncovalent bonds are relatively weak, but they can sum together to produce strong, highly specific interactions between molecules.

noncyclic photophosphorylation Photosynthetic process that produces both ATP and NADPH in plants and cyanobacteria.

nonenveloped virus Virus consisting of a nucleic acid core and protein capsid only.

nonpolar (apolar) Lacking any asymmetric accumulation of positive and negative charge. Nonpolar molecules are generally insoluble in water.

nonsense-mediated mRNA decay Mechanism for removing aberrant mRNAs containing in-frame internal stop codons before they can be translated.

Northern blotting Technique in which RNA fragments separated by electrophoresis are immobilized on a paper sheet. A specific RNA is then detected by hybridization with a labeled nucleic acid probe.

NO *see* **nitric oxide**

Notch Receptor protein involved in many instances of choice of cell fate in animal development, for example in the specification of nerve cells from ectodermal epithelium. Its ligands are cell-surface proteins such as Delta and Serrate.

notochord Stiff rod of mesoderm that runs along the back of all chordate embryos. In vertebrates it does not persist and becomes incorporated into the vertebral column.

NSF Protein with ATPase activity that disassembles a complex of a v-SNARE and a t-SNARE.

nuclear envelope Double membrane surrounding the nucleus. Consists of an outer and inner membrane and is perforated by nuclear pores.

nuclear export signal Sorting signal contained in the structure of molecules and complexes, such as RNA and new ribosomal subunits, that are transported from the nucleus to the cytosol through nuclear pore complexes.

nuclear lamin Protein subunit of the intermediate filaments of the nuclear lamina.

nuclear lamina Fibrous meshwork of proteins on the inner surface of the inner nuclear membrane. It is made up of a network of intermediate filaments formed from nuclear lamins.

nuclear localization signal (NLS) Signal sequences or signal patches found in proteins destined for the nucleus and which enable their selective transport into the nucleus from the cytosol through the nuclear pore complexes.

nuclear magnetic resonance *see* NMR

nuclear pore complex Large multiprotein structure forming a channel (the **nuclear pore**) through the nuclear envelope that allows selected molecules to move between nucleus and cytoplasm.

nuclear receptor superfamily Intracellular receptors for hydrophobic signal molecules such as steroids and retinoic acid. The receptor-ligand complex acts as a transcription factor in the nucleus.

nuclear transport Movement of macromolecules into or out of the nucleus mediated by nuclear transport receptors.

nucleation Critical stage in the assembly of a polymeric structure, such as a microtubule, at which a small cluster of monomers aggregates in the correct arrangement to initiate rapid polymerization. (*See* Panel 16–2, pp. 912–913.) More generally, the rate-limiting step in an assembly process.

nucleic acid RNA or DNA, a macromolecule consisting of a chain of nucleotides joined together by phosphodiester bonds.

nucleolar organizer Region of a chromosome containing a cluster of ribosomal RNA genes that gives rise to a nucleolus.

nucleolus Structure in the nucleus where ribosomal RNA is transcribed and ribosomal subunits are assembled.

nucleoporin Any of a number of different proteins that make up nuclear pore complexes.

nucleoside Molecule composed of a purine or pyrimidine base covalently linked to a ribose or deoxyribose sugar. (*See* Panel 2–6, pp. 120–121.)

nucleosome Beadlike structure in eucaryotic chromatin. It is composed of a short length of DNA wrapped around a core of histone proteins, and is the

fundamental structural unit of chromatin.

nucleotide Nucleoside with one or more phosphate groups joined in ester linkages to the sugar moiety. DNA and RNA are polymers of nucleotides. (See Panel 2–6, pp. 120–121.)

nucleus Prominent membrane-bounded organelle in a eucaryotic cell, containing DNA organized into chromosomes.

nurse cell Cell connected by cytoplasmic bridges to a developing oocyte and which thereby supplies it with ribosomes, mRNAs, and proteins needed for the development of the early embryo.

occluding junction Type of cell junction that seals cells together in an epithelium, forming a barrier through which even small molecules cannot pass.

Okazaki fragments Short lengths of DNA produced on the lagging strand during DNA replication. They are rapidly joined by DNA ligase to form a continuous DNA strand.

oligodendrocyte Type of glial cell in the vertebrate central nervous system that forms a myelin sheath around axons.

oligomer Short polymer, usually consisting (in a cell) of amino acids (oligopeptides), sugars (oligosaccharides), or nucleotides (oligonucleotides). (From Greek *oligos*, few, little.)

oligosaccharide Short linear or branched chain of covalently linked sugars (see Panel 2–4, pp. 116–117.) (See also **complex oligosaccharide**, **high-mannose oligosaccharide**, **N-linked oligosaccharide**, **O-linked glycosylation**.)

O-linked glycosylation Addition of an oligosaccharide chain to a protein through the OH group of a serine or threonine side chain.

oncogene An altered gene whose product can act in a dominant fashion to help make a cell cancerous. Typically, an oncogene is a mutant form of a normal gene (proto-oncogene) involved in the control of cell growth or division.

oocyte The developing egg. It is usually a large and immobile cell.

oogenesis Formation and maturation of oocytes in the ovary.

operator Short region of DNA in a bacterial chromosome that controls the transcription of an adjacent gene.

operon In a bacterial chromosome, a group of contiguous genes that are transcribed into a single mRNA molecule.

ORC see **origin recognition complex**

organelle Membrane-enclosed compartment in a eucaryotic cell that has a

distinct structure, macromolecular composition, and function. Examples are nucleus, mitochondrion, chloroplast, Golgi apparatus.

Organizer *see* **Spemann's Organizer**

origin recognition complex (ORC) Large protein complex that is bound to the DNA at origins of replication in eucaryotic chromosomes throughout the cell cycle.

osmolarity A term used to describe the concentration of a solute in terms of the osmotic pressure it can exert.

osmosis Net movement of water molecules across a semipermeable membrane driven by a difference in concentration of solute on either side. The membrane must be permeable to water but not to the solute molecules.

osteoblast Cell that secretes matrix of bone.

osteoclast Macrophage-like cell that erodes bone, enabling it to be remodeled during growth and in response to stresses throughout life.

outer membrane Outermost of the two membranes surrounding an organelle; the membrane adjacent to the cytosol.

outer nuclear membrane The outermost of the two nuclear membranes. It is continuous with the endoplasmic reticulum and is studded with ribosomes on its cytosolic face.

overlap microtubule In the mitotic or meiotic spindle, a microtubule interdigitating at the equator with the microtubules emanating from the other pole.

ovulation Release of an egg from the ovary.

ovum *see* **egg**

oxidation (verb oxidize) Loss of electrons from an atom, as occurs during the addition of oxygen to a molecule or when a hydrogen is removed. Opposite of reduction. (*See* [Figure 2–43](#).)

oxidative phosphorylation Process in bacteria and mitochondria in which ATP formation is driven by the transfer of electrons from food molecules to molecular oxygen. Involves the intermediate generation of a proton gradient (pH gradient) across a membrane and chemiosmotic coupling.

p53 Tumor suppressor gene found mutated in about half of human cancers. It encodes a gene regulatory protein that is activated by damage to DNA and is involved in blocking further progression through the cell cycle.

pachytene Third stage of division I of meiosis, in which synapsis is complete.

palindromic sequence Nucleotide sequence that is identical to its complementary strand when each is read in the same chemical direction—for example, GATC.

paracrine signaling Short-range cell-cell communication via secreted signal molecules that act on adjacent cells.

parthenogenesis Production of a new individual from an egg cell in the absence of fertilization by sperm.

passive transport Transport of a solute across a membrane down its concentration gradient or its electrochemical gradient, using only the energy stored in the gradient.

patch-clamp recording Electrophysiological technique in which a tiny electrode tip is sealed onto a patch of cell membrane, thereby making it possible to record the flow of current through individual ion channels in the patch.

pathogen (*adjective pathogenic*) An organism or other agent that causes disease.

PCR (polymerase chain reaction) Technique for amplifying specific regions of DNA by the use of sequence-specific primers and multiple cycles of DNA synthesis, each cycle being followed by a brief heat treatment to separate complementary strands.

peptide bond Chemical bond between the carbonyl group of one amino acid and the amino group of a second amino acid—a special form of amide linkage. Peptide bonds link amino acids together in proteins. (*See Panel 3–1, pp. 132–133.*)

peptide map Characteristic two-dimensional pattern (on paper or gel) formed by the separation of the mixture of peptides produced by the partial digestion of a protein.

peripheral lymphoid organ (secondary lymphoid organ) Lymphoid organ in which T cells and B cells interact with foreign antigens. Examples are spleen, lymph nodes, and mucosal-associated lymphoid tissue.

peripheral membrane protein Protein that is attached to one face of a membrane by noncovalent interactions with other membrane proteins, and which can be removed by relatively gentle treatments that leave the lipid bilayer intact.

peroxisome Small membrane-bounded organelle that uses molecular oxygen to oxidize organic molecules. Contains some enzymes that produce and others that degrade hydrogen peroxide (H₂O₂).

pH Common measure of the acidity of a solution: "p" refers to power of 10,

"H" to hydrogen. Defined as the negative logarithm of the hydrogen ion concentration in moles per liter (M). Thus on the **pH scale**, pH 3 (10^{-3} M H^+) is acidic and pH 9 (10^{-9} M H^+) is alkaline.

PH domain *see* **pleckstrin homology domain**

phage display Technique for detecting proteins that interact with each other by screening a protein against a library of genetically modified phage, each displaying a potential binding protein on their surface.

phage *see* **bacteriophage**

phagocyte General term for a professional phagocytic cell—that is, a cell such as a macrophage or neutrophil that is specialized to take up particles and microorganisms by phagocytosis.

phagocytosis Process by which particulate material is endocytosed ("eaten") by a cell. Prominent in carnivorous cells, such as *Amoeba proteus*, and in vertebrate macrophages and neutrophils. (From Greek *phagein*, to eat.)

phagosome Large intracellular membrane-bounded vesicle that is formed as a result of phagocytosis. Contains ingested extracellular material.

phase-contrast microscope Type of light microscope that exploits the interference effects that occur when light passes through material of different refractive indexes. Used to view living cells.

phenotype The observable character of a cell or an organism.

phosphatase Enzyme that removes phosphate groups from a molecule.

phosphatidylinositol 3-kinase (PI 3-kinase) A kinase involved in intracellular signaling pathways activated by a variety of cell-surface receptors. It phosphorylates inositol phospholipids at the 3 position of the inositol ring. (See [Figure 15–58](#).)

phosphatidylinositol An inositol phospholipid. (See [Figure 15–34](#).)

phosphodiester linkage Set of covalent chemical bonds formed when two hydroxyl groups are linked in ester linkage to the same phosphate group. This linkage joins adjacent nucleotides in RNA or DNA. (See [Figure 2–28](#).)

phosphoinositide *see* **inositol phospholipid**

phospholipase C- β (PLC- β) Enzyme bound to the cytoplasmic face of the plasma membrane that converts membrane phosphatidylinositol 4,5-bisphosphate to diacylglycerol (which remains in the plasma membrane) and inositol 1,4,5-trisphosphate (IP_3). It is activated by certain G proteins to trigger the inositol phospholipid signaling pathway.

- phospholipase C- γ (PLC- γ)** Like phospholipase C- β , an enzyme that cleaves inositol phospholipids to diacylglycerol and IP₃ to trigger the inositol phospholipid signaling pathway. Activated by certain receptor tyrosine kinases.
- phospholipid exchange protein** Water-soluble carrier protein that transfers a phospholipid molecule from one membrane to another.
- phospholipid** The main category of lipid molecules used to construct biological membranes. Generally composed of two fatty acids linked through glycerol phosphate to one of a variety of polar groups.
- phosphoprotein phosphatase** Enzyme that removes a phosphate group from a protein by hydrolysis.
- phosphorylation** Reaction in which a phosphate group becomes covalently coupled to another molecule.
- photochemical reaction center** The part of a photosystem that converts light energy into chemical energy.
- photon** Elementary particle of light and other electromagnetic radiation.
- photoreceptor** Cell or molecule that is sensitive to light.
- photosynthesis** Process by which plants, algae and some bacteria use the energy of sunlight to drive the synthesis of organic molecules from carbon dioxide and water.
- photosynthetic electron-transfer** Light-driven reactions in photosynthesis in which electrons move along the electron-transport chain in the thylakoid membrane, generating ATP and NADPH.
- photosystem** Multiprotein complex involved in photosynthesis that captures the energy of sunlight and converts it to useful forms of energy.
- phragmoplast** Structure made of microtubules and actin filaments that forms in the prospective plane of division of a plant cell and guides formation of the cell plate.
- phylogeny** Evolutionary history of an organism or group of organisms, often presented in chart form as a phylogenetic tree.
- pinocytosis** Type of endocytosis in which soluble materials are taken up from the environment and incorporated into vesicles for digestion. Literally, "cell drinking." (See also **fluid-phase endocytosis**.)
- PKA** *see* **cyclic AMP-dependent protein kinase**
- PKC** *see* **protein kinase C**
- plant growth regulator** Signal molecule (also known as a plant hormone) that

helps coordinate growth and development. Examples are ethylene, auxins, gibberellins, cytokines, abscisic acid, and the brassinosteroids.

plasma membrane Membrane that surrounds a living cell.

plasmid Small circular DNA molecule that replicates independently of the genome. Modified plasmids are used extensively as **plasmid vectors** for DNA cloning.

plasmodesma (plasmodesmata) Communicating cell–cell junction in plants in which a channel of cytoplasm lined by plasma membrane connects two adjacent cells through a small pore in their cell walls.

plastid Cytoplasmic organelle in plants, bounded by a double membrane, that carries its own DNA and is often pigmented. Chloroplasts are plastids.

platelet Cell fragment, lacking a nucleus, that breaks off from a megakaryocyte in the bone marrow and is found in large numbers in the bloodstream. It helps initiate blood clotting when blood vessels are injured.

PLC- β *see* **phospholipase C- β**

PLC- γ *see* **phospholipase C- γ**

pleckstrin homology domain (PH domain) Protein domain found in intracellular signaling proteins by which they bind to inositol phospholipids phosphorylated by PI 3-kinase.

ploidy The number of complete sets of chromosomes in a genome. Diploid organisms have two sets in their somatic cells, polyploid organisms more than two. Natural polyploidy is the result of previous duplications of the whole genome or the introduction of complete genomes from another species during evolution.

plus end The end of a microtubule or actin filament at which addition of monomers occurs most readily; the "fast-growing" end of a microtubule or actin filament. The plus end of an actin filament is also known as the barbed end. (See Panel 16–2, pp. 912–913.)

point mutation Change of a single nucleotide in DNA, especially in a region of DNA coding for protein.

polar In the electrical sense, describes a structure (for example, a chemical bond, chemical group, or molecule) with positive charge concentrated toward one end and negative charge toward the other as a result of an uneven distribution of electrons. Polar molecules are likely to be soluble in water.

polyisoprenoid– *see* **isoprenoid**

polymer Large molecule made by covalently linking multiple identical or similar units (monomers) together.

polymerase chain reaction *see* **PCR**

polymorphic Describes a gene with many different alleles, none of which is predominant in the population.

polypeptide Linear polymer composed of multiple amino acids. Proteins are large polypeptides, and the two terms can be used interchangeably.

polypeptide backbone The chain of repeating carbon and nitrogen atoms, linked by peptide bonds, in a polypeptide or protein. The side chains of the amino acids project from this backbone.

polyploid Describes a cell or an organism that contains more than two sets of homologous chromosomes.

polyribosome (polysome) Messenger RNA molecule to which are attached a number of ribosomes engaged in protein synthesis.

polysaccharide Linear or branched polymer of monosaccharides. They include glycogen, starch, hyaluronic acid, and cellulose.

polytene chromosome Giant chromosome in which the DNA has undergone repeated replication without separation into new chromosomes.

position effect Differences in gene expression that depend on the position of the gene on the chromosome and probably reflect differences in the state of the chromatin along the chromosome.

positional information Information supplied to or possessed by cells according to their position in a multicellular organism. A cell's internal record of its positional information is called its **positional value**.

positive control Type of control of gene expression in which the active DNA-binding form of the regulatory protein turns the gene on.

posterior Situated toward the tail end of the body.

posttranscriptional control Any control on gene expression that is exerted at a stage after transcription has begun.

posttranslational Describes any process involving a protein that occurs after protein synthesis is completed.

posttranslational modification The enzyme-catalyzed change to a protein made after it is synthesized. Examples are acetylation, cleavage, glycosylation, methylation, phosphorylation, and prenylation.

pre-B cell Immediate precursor of a B cell.

prenylation Covalent attachment of an isoprenoid lipid group to a protein.

preprophase band Circumferential band of microtubules and actin filaments that forms around a plant cell under the plasma membrane prior to mitosis and cell division.

primary immune response Adaptive immune response to an antigen that is made on first encounter with that antigen.

primary structure Sequence of monomer units in a linear polymer, such as the amino acid sequence of a protein.

primordial germ cell Cell set aside early in embryonic development that is a precursor to germ cells that give rise to gametes.

primosome A complex of DNA primase and DNA helicase that is formed on the lagging strand during DNA replication, improving the efficiency of replication.

prion An infectious abnormal form of a normal protein that is replicated in the host by forcing the normal proteins of the same type to adopt the aberrant structure.

prion disease Transmissible spongiform encephalopathies such as Kreutzfeld–Jacob disease in humans, scrapie in sheep and bovine spongiform encephalopathy (BSE) in cattle, that are apparently caused and transmitted by abnormal forms of a protein (prions).

probe Defined fragment of RNA or DNA, radioactively or chemically labeled, used to locate specific nucleic acid sequences by hybridization.

procaryote (prokaryote) Single-celled microorganism whose cells lack a well-defined, membrane-enclosed nucleus. The procaryotes comprise two of the major domains of living organisms—the Bacteria and the Archaea.

programmed cell death *see* **apoptosis**

prometaphase Phase of mitosis preceding metaphase in which the nuclear envelope breaks down and chromosomes first attach to the spindle.

promoter Nucleotide sequence in DNA to which RNA polymerase binds to begin transcription.

prophase First stage of mitosis, during which the chromosomes are condensed but not yet attached to a mitotic spindle.

protease (proteinase, proteolytic enzyme) Enzyme such as trypsin that degrades proteins by hydrolyzing some of their peptide bonds.

proteasome Large protein complex in the cytosol with proteolytic activity that is responsible for degrading proteins that have been marked for destruction by ubiquitylation or by some other means.

protein The major macromolecular constituent of cells. A linear polymer of amino acids linked together by peptide bonds in a specific sequence.

protein domain Portion of a protein that has a tertiary structure of its own. Larger proteins are generally composed of several domains, each connected to the next by short flexible regions of polypeptide chain.

protein glycosylation Posttranslational addition of oligosaccharide side chains to a protein.

protein kinase Enzyme that transfers the terminal phosphate group of ATP to a specific amino acid of a target protein.

protein kinase C (PKC) Ca^{2+} -dependent protein kinase that, when activated by diacylglycerol and an increase in the concentration of Ca^{2+} , phosphorylates target proteins on specific serine and threonine residues.

protein module *see* **module**

protein phosphatase *see* **phosphoprotein phosphatase**

protein phosphorylation The covalent addition of a phosphate group to a side chain of a protein catalyzed by a protein kinase.

protein translocator Membrane-bound protein that mediates the transport of another protein across an organelle membrane.

proteoglycan Molecule consisting of one or more glycosaminoglycan (GAG) chains attached to a core protein.

proteolysis Degradation of a protein by hydrolysis at one or more of its peptide bonds.

proteolytic enzyme *see* **protease**

protofilament A linear chain of protein subunits joined end to end, which associates laterally with other protofilaments to form cytoskeletal components such as microtubules and intermediate filaments.

proton Positively charged subatomic particle that forms part of an atomic nucleus. Hydrogen has a nucleus composed of a single proton (H^+).

proton-motive force Driving force that moves protons across a membrane as a result of an electrochemical proton gradient.

proto-oncogene Normal gene, usually concerned with the regulation of cell proliferation, that can be converted into a cancer-promoting oncogene by mutation.

protozoa Free-living or parasitic, nonphotosynthetic, single-celled, motile

eucaryotic organisms, such as *Paramecium* and *Amoeba*. Free-living protozoa feed on bacteria or other microorganisms.

pseudogene Gene that has accumulated multiple mutations that has rendered it inactive and nonfunctional.

pseudopodium (pseudopodia) Large cell-surface protrusion formed by amoeboid cells as they crawl. More generally, any dynamic actin-rich extension of the surface of an animal cell.

pulse-chase Technique for following the movement of a substance through a biochemical or cellular pathway, by briefly adding the radioactively labeled substance (the pulse) followed by the unlabeled substance (the chase).

pump Transmembrane protein that drives the active transport of ions or small molecules across the lipid bilayer.

purine One of the two categories of nitrogen-containing ring compounds found in DNA and RNA. Examples are adenine and guanine. (See Panel 2–6, pp. 120–121.)

pyrimidine One of the two categories of nitrogen-containing ring compounds found in DNA and RNA. Cytosine, thymine and uracil are pyrimidines. (See Panel 2–6, pp. 120–121.)

quaternary structure Three-dimensional relationship of the different polypeptide chains in a multisubunit protein or protein complex.

quinone (Q) Small, lipid soluble, mobile electron carrier molecule found in the respiratory and photosynthetic electron-transport chains. (See [Figure 14–24](#).)

Rab protein Any of a large family of monomeric GTPases present in the plasma membrane and organelle membranes that are involved in conferring specificity on vesicle docking.

radioactive isotope Form of an atom with an unstable nucleus that emits radiation as it decays.

Ran Monomeric GTPase present in both cytosol and nucleus that is required for the active transport of macromolecules into and out of the nucleus through nuclear pore complexes. Hydrolysis of GTP to GDP is thought to provide the energy required for this transport.

Ras protein The most famous member of a large family of GTP-binding proteins (called monomeric GTPases) that help relay signals from cell-surface receptors to the nucleus. Named for the *ras* gene, first identified in viruses that cause rat sarcomas.

reaction In chemistry, any process in which one molecule is converted into another by the removal or addition of atoms, or in which the arrangement of

atoms in a molecule or molecules is altered by a change in chemical bonds.

reading frame The phase in which nucleotides are read in sets of three to encode a protein. A messenger RNA molecule can be read in any one of three reading frames, only one of which will give the required protein. (See [Figure 6–51](#).)

RecA protein The prototype for a class of DNA-binding proteins that catalyze synapsis of DNA strands during genetic recombination.

receptor Protein that binds a specific extracellular signal molecule (ligand) and initiates a response in the cell. Cell-surface receptors, such as the acetylcholine receptor and the insulin receptor, are located in the plasma membrane, with their ligand-binding site exposed to the external medium. Intracellular receptors, such as steroid hormone receptors, bind ligands that diffuse into the cell across the plasma membrane.

receptor-mediated endocytosis Internalization of receptor-ligand complexes from the plasma membrane by endocytosis. It is used to take up some macromolecules, such as cholesterol-containing lipoproteins, from the extracellular fluid, and is also a means of recycling receptor proteins once they have bound their ligands.

recessive In genetics, refers to the member of a pair of alleles that fails to be expressed in the phenotype of the organism when the dominant allele is present. Also refers to the phenotype of an individual that has only the recessive allele.

recombinant DNA Any DNA molecule formed by joining DNA segments from different sources. Recombinant DNAs are widely used in the cloning of genes, in the genetic modification of organisms, and in molecular biology generally.

recombination Process in which DNA molecules are broken and the fragments are rejoined in new combinations. Can occur in the living cell—for example, through crossing-over during meiosis—or *in vitro* using purified DNA and enzymes that break and ligate DNA strands.

recycling endosomes Large intracellular membrane-bounded vesicle formed from a fragment of an endosome that is an intermediate stage on the passage of recycled receptors back to the cell membrane.

red blood cell *see* erythrocyte

redox pair Pair of molecules in which one acts as an electron donor and one as an electron acceptor in an oxidation-reduction reaction; for example, NADH (electron donor) and NAD⁺ (electron acceptor).

redox potential The affinity of a redox pair for electrons, generally measured as the voltage difference between an equimolar mixture of the pair and a

standard reference. NADH/NAD⁺ has a low redox potential and O₂/H₂ has a high redox potential (high affinity for electrons).

redox reaction A reaction in which one component becomes oxidized and the other reduced; an oxidation-reduction reaction.

reduction (verb reduce) Addition of electrons to an atom, as occurs during the addition of hydrogen to a molecule or the removal of oxygen from it. Opposite of oxidation. (See [Figure 2–43](#).)

regulatory sequence DNA sequence to which a gene regulatory protein binds to control the rate of assembly of the transcriptional complex at the promoter.

regulatory site Site on an enzyme, other than the active site, that binds a molecule that affects enzyme activity.

replication fork Y-shaped region of a replicating DNA molecule at which the two daughter strands are formed and separate.

replication origin Location on a DNA molecule at which duplication of the DNA begins.

replicative cell senescence Phenomenon observed in primary cell cultures as they age, in which cell proliferation slows down and finally halts.

repressor Protein that binds to a specific region of DNA to prevent transcription of an adjacent gene.

residue General term for the unit of a polymer. That portion of a sugar, amino acid, or nucleotide that is retained as part of the polymer chain during the process of polymerization.

respiration General term for a process in a cell involving the oxidative breakdown of sugars or other organic molecules, and requiring the uptake of O₂ while producing CO₂ and H₂O as waste products.

respiratory chain Electron-transport chain in the inner mitochondrial membrane that receives high-energy electrons derived from the citric acid cycle and generates the proton gradient across the membrane that is used to power ATP synthesis.

respiratory control Regulatory mechanism that controls the rate of electron transport in the respiratory chain according to need via a direct influence of the electrochemical proton gradient.

respiratory enzyme complex Any of the major protein complexes of the mitochondrial respiratory chain that act as electron-driven proton pumps to generate the proton gradient across the inner membrane.

resting membrane potential The membrane potential in equilibrium

conditions in which there is no net flow of ions across the plasma membrane.

restriction map Diagrammatic representation of a DNA molecule indicating the sites of cleavage by various restriction enzymes.

restriction nuclease (restriction enzyme) One of a large number of nucleases that can cleave a DNA molecule at any site where a specific short sequence of nucleotides occurs. Extensively used in recombinant DNA technology.

restriction point Important checkpoint in the mammalian cell cycle. Passage through the restriction point commits the cell to enter S phase. It corresponds to Start in the yeast cell cycle.

retrotransposon Type of transposable element that moves by being first transcribed into an RNA copy that is then reconverted to DNA by reverse transcriptase and inserted elsewhere in the chromosomes.

retrovirus RNA-containing virus that replicates in a cell by first making a double-stranded DNA intermediate.

reverse genetics Approach to discovering gene function that starts from the DNA (gene) and protein and then creates mutants to analyze the gene's function.

reverse transcriptase Enzyme first discovered in retroviruses that makes a double-stranded DNA copy from a single-stranded RNA template molecule.

rhodopsin G-protein-linked light-sensitive receptor protein in the rod photoreceptor cells of the retina.

ribonuclease Enzyme that cuts an RNA molecule by hydrolyzing one or more of its phosphodiester bonds.

ribonucleic acid *see* RNA

ribosomal RNA (rRNA) Any one of a number of specific RNA molecules that form part of the structure of a ribosome and participate in the synthesis of proteins. Often distinguished by their sedimentation coefficient, such as 28S rRNA or 5S rRNA.

ribosome Particle composed of ribosomal RNAs and ribosomal proteins that associates with messenger RNA and catalyzes the synthesis of protein.

ribozyme RNA with catalytic activity.

RNA (ribonucleic acid) Polymer formed from covalently linked ribonucleotide monomers. (*See also* messenger RNA, ribosomal RNA, transfer RNA.)

RNA editing Production of a functional mRNA by insertion or alteration of individual nucleotides in an RNA molecule after it is synthesized.

RNA interference (RNAi) Selective intracellular degradation of RNA that is intended to remove foreign RNAs, such as those of viruses. Fragments cleaved from free double-stranded RNA direct the degradative mechanism to other similar RNA sequences. Widely exploited in a technique used to silence the expression of selected genes.

RNA polymerase II holoenzyme Large pre-asssembled complex of RNA polymerase II, most of the general transcription factors required for its function, and the mediator protein complex.

RNA polymerase Enzyme that catalyzes the synthesis of an RNA molecule on a DNA template from nucleoside triphosphate precursors. (See [Figure 6–8](#).)

RNA primer Short stretch of RNA synthesized on a DNA template. It is required by DNA polymerases to start their DNA synthesis.

RNA processing control Control of gene expression by controlling how the RNA transcript is spliced or otherwise processed.

RNA splicing Process in which intron sequences are excised from RNA transcripts in the nucleus during formation of messenger and other RNAs.

RNAi *see* **RNA interference**

rod photoreceptor (rod) Photoreceptor cell type in the retina that is responsible for noncolor vision in dim light.

rough endoplasmic reticulum (rough ER) Endoplasmic reticulum with ribosomes on its cytosolic surface. Involved in the synthesis of secreted and membrane-bound proteins.

rRNA *see* **ribosomal RNA**

rRNA gene Gene that specifies a ribosomal RNA (rRNA).

S phase Period of a eucaryotic cell cycle in which DNA is synthesized.

Saccharomyces Genus of yeasts that reproduce asexually by budding or sexually by conjugation. Economically important in brewing and baking, they are also widely used in genetic engineering and as simple model organisms in the study of eucaryotic cell biology.

sarcoma Cancer of connective tissue.

sarcomere Repeating unit of a myofibril in a muscle cell, composed of an array of overlapping thick (myosin) and thin (actin) filaments between two adjacent Z discs.

sarcoplasmic reticulum Network of internal membranes in the cytoplasm of a muscle cell that contains high concentrations of sequestered Ca^{2+} which is

released into the cytosol during muscle excitation.

satellite DNA Regions of highly repetitive DNA from a eucaryotic chromosome, usually identifiable by its unusual nucleotide composition. Satellite DNA is not transcribed and has no known function.

saturated Describes a molecule containing carbon–carbon bonds that has only single covalent bonds.

scaffold protein Protein that organizes groups of interacting intracellular signaling proteins into signaling complexes.

scanning electron microscope Type of electron microscope that produces an image of the surface of an object.

S-Cdk Complex formed in vertebrate cells by an S-cyclin and the corresponding cyclin-dependent kinase (Cdk).

Schwann cell Glial cell responsible for forming myelin sheaths in the peripheral nervous system.

SDS polyacrylamide gel electrophoresis (SDS-PAGE) Type of electrophoresis in which the protein mixture to be separated is run through a gel containing the detergent sodium dodecyl sulfate (SDS) which unfolds the proteins and frees them from association with other molecules.

second messenger Small molecule that is formed in or released into the cytosol in response to an extracellular signal and helps to relay the signal to the interior of the cell. Examples include cAMP, IP₃, and Ca²⁺.

secondary immune response Adaptive immune response to an antigen that is made on a second or subsequent encounter with a given antigen. It is more rapid in onset, stronger, and more specific than the primary immune response.

secondary structure Regular local folding pattern of a polymeric molecule. In proteins, α helices and β sheets.

secretory vesicle Membrane-bounded organelle in which molecules destined for secretion are stored prior to release. Sometimes called secretory granule because darkly staining contents make the organelle visible as a small solid object.

section A very thin slice of tissue, suitable for viewing under the microscope.

selectin Member of a family of cell-surface carbohydrate-binding proteins that mediate transient, Ca²⁺-dependent cell-cell adhesion in the bloodstream, for example between white blood cells and the endothelium of the blood vessel wall.

selectivity filter That part of an ion channel structure that determines which

ions it can transport.

septate junction Main type of occluding cell junction in invertebrates; their structure is distinct from that of vertebrate tight junctions.

serine protease Type of protease that has a reactive serine in the active site.

sex chromosome Chromosome that may be present or absent, or present in a variable number of copies, according to the sex of the individual. In mammals, the X and Y chromosomes.

sexual reproduction Type of reproduction in which the genomes of two individuals are mixed in the formation of a new organism. Individuals produced by sexual reproduction differ from either of their parents and from each other.

SH2 domain Src homology region 2, a protein domain present in many signaling proteins; it binds a short amino acid sequence containing a phosphotyrosine.

side chain The part of an amino acid that differs between different amino acids, giving the amino acid its unique physical and chemical properties.

signal molecule Extracellular or intracellular molecule that cues the response of a cell to the behavior of other cells or objects in the environment.

signal patch Protein sorting signal that consists of a specific three-dimensional arrangement of atoms on the folded protein's surface.

signal peptidase Enzyme that removes a terminal signal sequence from a protein once the sorting process is complete.

signal-recognition particle (SRP) Ribonucleoprotein particle that binds an ER signal sequence on a partially synthesized polypeptide chain and directs the polypeptide and its attached ribosome to the endoplasmic reticulum.

signal sequence Short continuous sequence of amino acids that determines the eventual location of a protein in the cell. An example is the N-terminal sequence of 20 or so amino acids that directs nascent secretory and transmembrane proteins to the endoplasmic reticulum.

signal transduction Relaying of a signal by conversion from one physical or chemical form to another. In cell biology, the process by which a cell converts an extracellular signal into a response.

single-nucleotide polymorphism (SNP) Variation between individuals at certain nucleotide positions in the genome.

single-pass transmembrane protein Membrane protein in which the polypeptide chain crosses the lipid bilayer only once.

single-strand DNA-binding protein Protein that binds to the single strands of the opened-up DNA double helix, preventing helical structures from reforming while the DNA is being replicated.

sister chromatid *see* **chromatid**

site-directed mutagenesis Technique by which a mutation can be made at a particular site in DNA.

site-specific recombination Type of recombination that does not require extensive similarity in the two DNA sequences undergoing recombination. Can occur between two different DNA molecules or within a single DNA molecule.

small intracellular mediator *see* **second messenger**

small nuclear RNA (snRNA) Small RNA molecules that are complexed with proteins to form the ribonucleoprotein particles involved in RNA splicing.

smooth endoplasmic reticulum (smooth ER) Region of the endoplasmic reticulum not associated with ribosomes. It is involved in lipid synthesis.

smooth muscle cell Type of long, spindle-shaped mononucleate muscle cell making up the muscular tissue found in the walls of arteries and of the intestine and other viscera, and in some other locations of the vertebrate body. Called "smooth" because it lacks the striated myofibrils of skeletal and cardiac muscle cells.

SNAREs Large family of transmembrane proteins present in organelle membranes and the vesicles derived from them. They are involved in guiding vesicles to their correct destinations. They exist in pairs — a v-SNARE in the vesicle membrane that binds specifically to a complementary t-SNARE in the target membrane.

SNP *see* **single-nucleotide polymorphism**

snRNA *see* **small nuclear RNA**

solute Any molecule that is dissolved in a liquid. The liquid is called a solvent.

somatic cell Any cell of a plant or animal other than a germ cell or germ-cell precursor. (From Greek *soma*, body.)

somite One of a series of paired blocks of mesoderm that form during early development and lie on either side of the notochord in a vertebrate embryo. They give rise to the vertebral column, muscles and associated connective tissue. Each somite produces the musculature of one vertebral segment, plus associated connective tissue.

sorting signal Amino acid sequence that directs the delivery of a protein to a specific location outside the cytosol.

Southern blotting Technique in which DNA fragments separated by electrophoresis are immobilized on a paper sheet. Specific fragments are then detected with a labeled nucleic acid probe. (Named after E.M. Southern, inventor of the technique.)

spectrin Abundant protein associated with the cytosolic side of the plasma membrane in red blood cells, forming a rigid network that supports the membrane.

Spemann's Organizer Specialized tissue at the dorsal lip of the blastopore in an amphibian embryo; a source of signals that help to orchestrate formation of the embryonic body axis. (After H. Spemann and H. Mangold, co-discoverers.)

sperm (spermatozoon, spermatozoa) The mature male gamete in animals. It is motile and usually small compared with the egg.

spermatogenesis Development of sperm.

spindle-attachment checkpoint Checkpoint that operates during mitosis to ensure that all chromosomes are properly attached to the spindle before sister-chromatid separation starts.

spliceosome Large assembly of RNA and protein molecules that performs pre-mRNA splicing in eucaryotic cells.

Src family Family of cytoplasmic tyrosine kinases (pronounced "sark") that associate with the cytoplasmic domains of some enzyme-linked receptors (for example, the T cell antigen receptor) that lack intrinsic tyrosine kinase activity. They transmit a signal onwards by phosphorylating the receptor itself and other signaling proteins.

SRP *see* **signal-recognition particle**

standard free-energy change (ΔG°) Free-energy change of two reacting molecules at standard temperature and pressure when all components are present at a concentration of 1 mole per liter.

starch Polysaccharide composed exclusively of glucose units, used as an energy storage material in plant cells.

start-transfer signal Short amino-acid sequence that enables a polypeptide chain to start being translocated across the endoplasmic reticulum membrane through a protein translocator. Multipass membrane proteins have both N-terminal (signal sequence) and internal start-transfer signals.

stem cell Relatively undifferentiated cell that can continue dividing indefinitely, throwing off daughter cells that can undergo terminal differentiation into particular cell types.

stereocilium A large, rigid microvillus found in "organ pipe" arrays on the

apical surface of hair cells in the ear. A stereocilium contains a bundle of actin filaments, rather than microtubules, and is thus not a true cilium.

steroid Hydrophobic lipid molecule with a characteristic four-ringed structure. Many important hormones such as estrogen and testosterone are steroids. (See Panel 2–5, pp. 118–119.)

stimulatory G protein (G_s) G protein that, when activated, activates the enzyme adenylyl cyclase and thus stimulates the production of cyclic AMP.

stop-transfer signal Hydrophobic amino acid sequence that halts translocation of a polypeptide chain through the endoplasmic reticulum membrane, thus anchoring the protein chain in the membrane (See [Figure 12–49](#)).

strand-directed mismatch repair *see* **mismatch repair**

striated muscle Muscle composed of transversely striped (striated) myofibrils. Skeletal and heart muscle of vertebrates are the best-known examples.

stroma (1) The connective tissue in which a glandular or other epithelium is embedded. (2) The large interior space of a chloroplast, containing enzymes that incorporate CO_2 into sugars.

structural gene Region of DNA that codes for a protein or for an RNA molecule that forms part of a structure or has an enzymatic function. Distinguished from regions of DNA that regulate gene expression.

substrate Molecule on which an enzyme acts.

substratum Solid surface to which a cell adheres.

subunit Component of a multicomponent complex—for example, one protein component of a protein complex or one polypeptide chain of a multichain protein.

sucrose Disaccharide composed of one glucose unit and one fructose unit. The major form in which glucose is transported between plant cells.

sugar Small carbohydrates with a monomer unit of general formula $(CH_2O)_n$. Examples are the monosaccharides glucose, fructose and mannose, and the disaccharide sucrose (composed of a molecule of glucose and one of fructose linked together).

sulfhydryl (thiol, $-SH$) Chemical group containing sulfur and hydrogen found in the amino acid cysteine and other molecules. Two sulfhydryls can join to produce a disulfide bond.

supercoiled DNA Region of DNA in which the double helix is further twisted on itself. (See [Figure 6–20](#).)

survival factor Extracellular signal required for a cell to survive; in its absence the cell will undergo apoptosis and die.

symbiosis Intimate association between two organisms of different species from which both derive a long-term selective advantage.

symporter Carrier protein that transports two types of solute across the membrane in the same direction.

synapse Communicating cell–cell junction that allows signals to pass from a nerve cell to another cell. In a chemical synapse the signal is carried by a diffusible neurotransmitter; in an electrical synapse a direct connection is made between the cytoplasm of the two cells via gap junctions.

synapsis (1) In genetic recombination, the initial formation of base pairs between complementary DNA strands in different DNA molecules that occurs at sites of crossing-over between chromosomes. (2) In meiosis, the pairing of maternal and paternal copies of a chromosome as they become attached to each other along their length.

synaptic signaling Type of cell–cell communication that occurs across chemical synapses in the nervous system.

synaptic vesicle Small neurotransmitter-filled secretory vesicle formed at the axon terminals of nerve cells and whose contents are released into the synaptic cleft by exocytosis when an action potential reaches the axon terminal.

synaptonemal complex Structure that holds paired chromosomes together during prophase I of meiosis and promotes genetic recombination.

syncytium Mass of cytoplasm containing many nuclei enclosed by a single plasma membrane. Typically the result either of cell fusion or of a series of incomplete division cycles in which the nuclei divide but the cell does not.

synteny The presence in different species of regions of chromosomes with the same genes in the same order.

T cell (T lymphocyte) Type of lymphocyte responsible for cell-mediated immunity; includes both cytotoxic T cells and helper T cells.

TATA box Consensus sequence in the promoter region of many eucaryotic genes that binds a general transcription factor and hence specifies the position at which transcription is initiated.

TCA cycle *see* **citric acid cycle**

telomerase Enzyme that elongates telomere sequences in DNA.

telomere End of a chromosome, associated with a characteristic DNA sequence that is replicated in a special way. Counteracts the tendency of the

chromosome otherwise to shorten with each round of replication. (From Greek *telos*, end.)

telophase Final stage of mitosis in which the two sets of separated chromosomes decondense and become enclosed by nuclear envelopes.

temperature-sensitive (ts) mutant Organism or cell carrying a genetically altered protein (or RNA molecule) that performs normally at one temperature but is abnormal at another (usually higher) temperature.

template A single strand of DNA or RNA whose nucleotide sequence acts as a guide for the synthesis of a complementary strand.

terminator Signal in bacterial DNA that halts transcription.

tertiary structure Complex three-dimensional form of a folded polymer chain, especially a protein or RNA molecule.

TGF- β superfamily *see* **transforming growth factor- β superfamily**

TGN *see* **trans Golgi network (TGN)**

thioester bond High-energy bond formed by a condensation reaction between an acid (acyl) group and a thiol group ($-\text{SH}$); seen, for example, in acetyl CoA and in many enzyme-substrate complexes.

thiol *see* **sulfhydryl**

thylakoid Flattened sac of membrane in a chloroplast that contains chlorophyll and other pigments and carries out the light-trapping reactions of photosynthesis. Stacks of thylakoids form the grana of chloroplasts.

tight junction Cell–cell junction that seals adjacent epithelial cells together, preventing the passage of most dissolved molecules from one side of the epithelial sheet to the other.

TIM complexes Protein translocators in the mitochondrial inner membrane. The TIM23 complex mediates the transport of proteins into the matrix and the insertion of some proteins into the inner membrane; the TIM22 complex mediates the insertion of a subgroup of proteins into the inner membrane.

Toll-like receptor family (TLR) Important family of mammalian pattern recognition receptors abundant on macrophages, neutrophils and the epithelial cells of the gut. They recognize pathogen-associated immunostimulants such as lipopolysaccharide and peptidoglycan.

TOM complex Multisubunit protein complex that transports proteins across the mitochondrial outer membrane.

topoisomerase (DNA topoisomerase) Enzyme that makes reversible cuts in a double-helical DNA molecule for the purpose of removing knots or unwinding

excessive twists.

tracer Molecule or atom that has been labeled either chemically or radioactively so that it can be followed in a biochemical process or readily located in a cell or tissue.

trans face Face of a Golgi stack at which material leaves the organelle for the cell surface or another cell compartment. It is adjacent to the *trans* Golgi network.

trans Golgi network (TGN) Network of interconnected cisternae and tubules at the *trans* face of the Golgi apparatus, through which material is transferred out of the Golgi.

transcellular transport Transport of solutes, such as nutrients, across an epithelium, by means of membrane transport proteins in the apical and basal faces of the epithelial cells.

transcript RNA product of DNA transcription.

transcription (DNA transcription) Copying of one strand of DNA into a complementary RNA sequence by the enzyme RNA polymerase.

transcription attenuation Inhibition of gene expression in bacteria by the premature termination of transcription.

transcription factor Term loosely applied to any protein required to initiate or regulate transcription in eucaryotes. Includes both gene regulatory proteins as well as the general transcription factors.

transcriptional control Control of of gene expression by controlling when and how often the gene is transcribed.

transcytosis The uptake of material at one face of a cell by endocytosis, its transfer across a cell in vesicles, and its discharge from another face by exocytosis.

transfection Introduction of a foreign DNA molecule into a eucaryotic cell. It is usually followed by expression of one or more genes in the newly introduced DNA.

transfer RNA (tRNA) Set of small RNA molecules used in protein synthesis as an interface (adaptor) between messenger RNA and amino acids. Each type of tRNA molecule is covalently linked to a particular amino acid.

transforming growth factor- β superfamily (TGF- β superfamily) Large family of structurally related, secreted proteins that act as hormones and local mediators to control a wide range of functions in animals, including during development. It includes TGF- β s, activins, and bone morphogenetic proteins (BMPs).

transgenic organism Plant or animal that has stably incorporated one or more genes from another cell or organism and can pass them on to successive generations.

transition state Structure that forms transiently in the course of a chemical reaction and has the highest free energy of any reaction intermediate. Its formation is a rate-limiting step in the reaction.

translation (RNA translation) Process by which the sequence of nucleotides in a messenger RNA molecule directs the incorporation of amino acids into protein. It occurs on a ribosome.

translational control Control of gene expression by selection of which mRNAs in the cytoplasm are translated by ribosomes.

translocation Type of mutation in which a portion of one chromosome is broken off and attached to another.

transmembrane protein Membrane protein that extends through the lipid bilayer, with part of its mass on either side of the membrane.

transmitter-gated ion channel Ion channel in the postsynaptic plasma membranes of nerve and muscle cells that opens only in response to the binding of a specific extracellular neurotransmitter. The resulting inflow of ions leads to the generation of a local electrical signal in the postsynaptic cell.

transposable element Segment of DNA that can move from one position in a genome to another. Also called a transposon.

transposition The movement of a DNA sequence from one site to another within the genome. *See also cut-and-paste transposition.*

trans-splicing Type of RNA splicing present in a few eucaryotic organisms in which exons from two separate RNA molecules are joined together to form an mRNA.

treadmilling The process by which a polymeric protein filament is maintained at constant length by addition of protein subunits at one end and loss of subunits at the other. (*See Panel 16–2, pp. 912–913.*)

triacylglycerol Molecule composed of three fatty acids esterified to glycerol. The main constituent of fat droplets in animal tissues (where the fatty acids are saturated) and of vegetable oils (where the fatty acids are mainly unsaturated). Also known as triglyceride. (*See Panel 2–5, pp. 118–119.*)

tricarboxylic acid (TCA) cycle *see citric acid cycle*

trimeric GTP-binding protein *see GTP-binding protein*

tRNA *see transfer RNA*

t-SNARE *see* **SNAREs**

tubulin The protein subunit of microtubules.

tumor progression The process by which an initial mildly disordered cell behavior gradually evolves into a full-blown cancer.

tumor suppressor gene Gene that appears to prevent formation of a cancer. Loss-of-function mutations in such genes enhance susceptibility to cancer.

two-dimensional gel electrophoresis Type of electrophoresis in which the protein mixture is run first in one direction and then in a direction at right angles to the first. It enables better separation of individual proteins.

two-hybrid system Technique for identifying interacting proteins using genetically engineered yeast cells.

type III secretion system A bacterial system for delivering toxic proteins into the cells of their host.

ubiquitin Small, highly conserved protein present in all eucaryotic cells that becomes covalently attached to lysines of other proteins. Attachment of a short chain of ubiquitins to such a lysine tags a protein for intracellular proteolytic destruction by a proteasome.

ubiquitin ligase Any one of a large number of enzymes that attach ubiquitin to a protein, thus marking it for destruction in a proteasome. The process catalyzed by a ubiquitin ligase is called ubiquitylation.

unfolded protein response Cellular response triggered by an accumulation of misfolded proteins in the endoplasmic reticulum. It involves increased transcription of ER chaperones and degradative enzymes.

uniporter Carrier protein that transports a single solute from one side of the membrane to the other.

unsaturated Describes a molecule that contains one or more double or triple carbon-carbon bonds, such as isoprene or benzene.

V gene segment Gene segment encoding most of the variable region of the polypeptide chains of immunoglobulins and T cell receptors.

V (D) J joining Recombination process by which gene segments are brought together to form a functional gene for a polypeptide chain of an immunoglobulin or T cell receptor.

vacuole Very large fluid-filled vesicle found in most plant and fungal cells, typically occupying more than a third of the cell volume.

van der Waals attraction Type of (individually weak) noncovalent bond that is formed at close range between nonpolar atoms.

variable region Region of an immunoglobulin light or heavy chain that differs from molecule to molecule; it comprises the antigen-binding site.

vector In cell biology, the DNA of an agent (virus or plasmid) used to transmit genetic material to a cell or organism. (See also **cloning vector**, **expression vector**.)

vegetal pole The end at which most of the yolk is located in an animal egg. The end opposite the animal pole.

ventral Situated toward the belly surface of an animal, or towards the underside of a wing or leaf.

vesicle Small, membrane-bounded, spherical organelle in the cytoplasm of a eucaryotic cell.

vesicular transport Transport of proteins from one cellular compartment to another by means of membrane-bounded intermediaries such as vesicles or organelle fragments.

virulence gene Gene that contributes to an organism's ability to cause disease.

virus Particle consisting of nucleic acid (RNA or DNA) enclosed in a protein coat and capable of replicating within a host cell and spreading from cell to cell. Many viruses cause disease.

voltage-gated cation channel Type of ion channel found in the membranes of excitable cells (such as nerve cells and muscle) which opens in response to a shift in membrane potential past a threshold value.

v-SNARE *see* **SNAREs**

Western blotting Technique by which proteins are separated by electrophoresis and immobilized on a paper sheet and then analyzed, usually by means of a labeled antibody.

white blood cell (leucocyte) General name for all the nucleated blood cells lacking hemoglobin. Includes lymphocytes, neutrophils, eosinophils, basophils, and monocytes.

wild-type Normal, nonmutant form of an organism; the form found in nature (in the wild).

Xenopus laevis (South African clawed toad) Species of frog (not toad) frequently used in studies of early vertebrate development.

XIC *see* **X-inactivation center**

X-inactivation Inactivation of one copy of the X chromosome in the somatic cells of female mammals.

X-inactivation center (XIC) Site in an X chromosome at which inactivation is initiated and spreads outwards.

X-ray crystallography Technique for determining the three-dimensional arrangement of atoms in a molecule based on the diffraction pattern of X-rays passing through a crystal of the molecule.

yeast Common term for several families of unicellular fungi. Includes species used for brewing beer and making bread, as well as pathogenic species (that is, species that cause disease).

yolk Nutritional reserves rich in lipids, proteins and polysaccharides, present in the eggs of many animals.

Z disc (Z line) Platelike region of a muscle sarcomere to which the plus ends of actin filaments are attached. Seen as a dark transverse line in micrographs.

zinc finger DNA-binding structural motif present in many gene regulatory proteins. Composed of a loop of polypeptide chain held in a hairpin bend bound to a zinc atom.

zona pellucida Glycoprotein layer on the surface of the unfertilized egg. It is often a barrier to fertilization across species.

zygote Diploid cell produced by fusion of a male and female gamete. A fertilized egg.

zygotene Second stage of division I of meiosis, in which the synaptonemal complex begins to form between the two sets of sister chromatids in each bivalent chromosome.
